(Received 2 March 2016; published 7 June 2016)

We report the results of a study aimed at quantifying the impact on the oscillation analysis of the uncertainties associated with the description of the neutrino-nucleus cross section in the two-particle–twohole sector. The results of our calculations, based on the kinematic method of energy reconstruction and carried out comparing two data-driven approaches, show that the existing discrepancies in the neutrino cross sections have a sizable effect on the extracted oscillation parameters, particularly in the antineutrino channel.

DOI: [10.1103/PhysRevD.93.113004](http://dx.doi.org/10.1103/PhysRevD.93.113004)

The T2K Collaboration has recently reported two measurements of the inclusive cross section for charged-current (CC) muon-neutrino scattering off the hydrocarbon target, CH [\[1,2\]](#page-4-0). Since they are flux-averaged at different meanenergy values, the T2K results show the cross section as a function of neutrino energy with minimal dependence on nuclear models.

While the T2K data are lower by ∼20% than the fluxaveraged hydrocarbon result previously obtained by the SciBooNE Collaboration [\[3\]](#page-4-1), with the difference exceeding the experimental uncertainties, they appear to be in good agreement with the expectations based on the ${}^{12}_{6}C(\nu_{\mu}, \mu^{-})X$ cross section measured at higher energies by the NOMAD experiment [\[4\]](#page-4-2).

At the kinematics of the T2K and SciBooNE experiments, momentum transfers **q** are typically large enough for neutrinos—probing the nuclear interior with the spatial resolution $\sim 1/|\mathbf{q}|$ —to scatter off individual (bound) nucleons. On the other hand, the dominant contribution to the cross section comes from low energy transfers ω , insufficient to produce pions, and the quasielastic (QE) mechanisms of interaction,

$$
\nu_{\ell} + n \to \ell^{-} + p, \quad \bar{\nu}_{\ell} + p \to \ell^{+} + n, \tag{1}
$$

play the most important role.

In the past, CC QE processes were considered well understood theoretically and used to determine the flux normalization [\[5\]](#page-4-3). Recently, however, it has become apparent that this is not the case to the extent required by precise oscillation experiments [\[6\]](#page-4-4). For example, while the CC QE cross sections of carbon reported by the MiniBooNE Collaboration [\[7,8\]](#page-4-5) turn out to be higher than those of free nucleons, the corresponding NOMAD data [\[9\]](#page-5-0) show the cross-sections' reduction arising from nuclear effects. Although those puzzling discrepancies have received a great deal of theoretical interest, their interpretation is not fully established so far.

In particular, while a non-negligible role of CC QE reaction mechanisms involving more than one nucleon is now generally acknowledged, and important theoretical progress has been achieved [\[10\]](#page-5-1), an ab initio estimate of the corresponding cross sections is not yet available. Since those multinucleon mechanisms involve predominantly two nucleons, hereafter we refer to them as two-particle– two-hole $(2p2h)$ processes.

For nuclear targets ranging from carbon to iron, a growing body of experimental evidence [\[7,11](#page-4-5)–15] shows that $2p2h$ effects on the differential QE cross sections can be effectively accounted for by increasing the value of the axial mass M_A , typically to ~1.2 GeV, with respect to $M_A = 1.03$ GeV extracted predominantly from deuterium measurements [\[16\].](#page-5-2) Note that as the axial mass is the cutoff parameter driving the axial form factor's dependence on $Q^2 = \mathbf{q}^2 - \omega^2$, its changes affect both the differential and total cross sections.

In this article, we discuss uncertainties of the $2p2h$ cross sections for carbon and quantify their effect on the oscillation analysis for an experimental setup similar to that of T2K [\[17\]](#page-5-3). We consider a disappearance experiment running in both neutrino and antineutrino mode with the same flux [\[18\],](#page-5-4) peaked at ∼600 MeV. To describe the ground-state properties of the target nucleus, we use the realistic spectral function (SF) of Ref. [\[19\].](#page-5-5) This approach allows an accurate estimate of QE scattering induced by one-nucleon currents, as shown by an extensive comparison to electron-scattering data in Ref. [\[20\]](#page-5-6). To account for an increase of the CC QE cross sections due to $2p2h$ processes, we use two data-driven phenomenological

ankowski@vt.edu

methods: (i) an increased value of the axial mass, yielding results consistent with the T2K [\[1,2\]](#page-4-0), NOMAD [\[4,9\],](#page-4-2) and MINERvA $[21,22]$ data, and (ii) the $2p2h$ estimate in the GENIE Monte Carlo generator [\[23\],](#page-5-8) determined from the MiniBooNE data [\[7\]](#page-4-5) and in agreement with the experimental cross sections extracted from SciBooNE [\[3\]](#page-4-1).

We emphasize that although our study is performed for a setup similar—not identical—to that of T2K, it does not follow the analysis of that experiment. For example, applying a generalization of the kinematic method of energy reconstruction [\[24\],](#page-5-9) we include in the oscillation analysis events of all types, instead of the CC QE event sample alone. The rationale for considering the T2K-like kinematics is its importance for the next generation of oscillation experiments [\[25,26\]](#page-5-10).

Consequences of $2p2h$ effects for the CC QE cross sections have been analyzed within a few effective approaches. The calculations of Martini et al. [\[27](#page-5-11)–30], based on the local Fermi gas model and the random-phase approximation (RPA), extend the treatment of multinucleon contributions to the electromagnetic responses of iron developed by Alberico et al. [\[31\]](#page-5-12) to the case of neutrino interactions with carbon and to a broader kinematic region.

While employing the local Fermi gas model and the RPA scheme, the approach of Nieves *et al.* [32–[35\]](#page-5-13) differs from that of Martini et al. by using effective interactions, the parameters of which were fixed in earlier studies of photon, electron, and pion scattering off nuclei. At the MiniBooNE kinematics, the CC QE ν_{μ} ($\bar{\nu}_{\mu}$) cross sections obtained by Nieves *et al.* are lower by \sim 10% (\sim 15%) with respect to those calculated by Martini et al.

To extend their superscaling approach and include the contributions of processes involving two-nucleon currents, Amaro et al. [\[36,37\]](#page-5-14) and Megias et al. [\[38,39\]](#page-5-15) have previously estimated the $2p2h$ cross sections within the relativistic Fermi gas model accounting for the vector meson-exchange currents only. Recently, the efforts to also include the axial part in the response functions have been completed [\[40\]](#page-5-16).

In the Giessen Boltzmann-Uehling-Uhlenbeck transport model, the $2p2h$ contribution to the CC QE cross sections is obtained from a fit to the MiniBooNE data performed by Lalakulich *et al.* [\[41\],](#page-5-17) using a physically well-motivated ansatz.

The GENIE Monte Carlo generator [\[42\]](#page-6-0) simulates $2p2h$ events following the empirical procedure developed by Dytman [\[23\]](#page-5-8), based on the one derived for electron scattering in Ref. [\[43\]](#page-6-1). The kinematics of the produced lepton is distributed according to the magnetic contribution to the elementary cross section and, as a consequence, turns out to be the same for neutrinos and antineutrinos. The $2p2h$ strength is set to decrease linearly for neutrino energy larger than 1 GeV and to vanish at 5 GeV, consistently with both the MiniBooNE [\[7\]](#page-4-5) and NOMAD [\[9\]](#page-5-0) data. GENIE is employed in data analysis by a number of neutrino experiments [\[44\]](#page-6-2), as well as in phenomenological estimates of the impact of nuclear effects on the determination of oscillation parameters, following the pioneering studies carried out by the authors of Ref. [\[45\]](#page-6-3).

In this article, we analyze how the oscillation analysis may be affected by uncertainties in the description of $2p2h$ contributions to the CC QE cross sections, comparing two estimates obtained from different approaches. In the first case, we apply an effective value of the axial mass $M_A =$ 1.2 GeV to account for the modifications of the QE cross sections due to $2p2h$ reaction mechanisms in a purely phenomenological manner ("effective" calculations). In the second case, we add the $2p2h$ results obtained using GENIE 2.8.0 [\[23\]](#page-5-8) to the QE calculations performed using the SF approach with $M_A = 1.03$ GeV, as implemented in the $ν$ T package of additional modules [\[46\]](#page-6-4) ("GENIE + $ν$ T" calculations).

The obtained total CC QE cross sections are compared to the experimental data in Fig. [1.](#page-2-0) It clearly appears that the effective calculations are in good agreement with the NOMAD [\[9\]](#page-5-0) and MINERvA [\[21,22\]](#page-5-7) results for both neutrinos and antineutrinos. They also reproduce the energy dependence of the MiniBooNE data [\[7,8\]](#page-4-5), but not their absolute normalization. To better illustrate this feature, we have divided the MiniBooNE cross sections by a factor of 1.2, consistent with the ratio of the detected to predicted events of 1.21 ± 0.24 reported from the first MiniBooNE analysis [\[12\].](#page-5-18)

While for neutrinos, the $2p2h$ contribution from GENIE is in very good agreement with the MiniBooNE data, for antineutrinos it overestimates the experimental points, in spite of being added to the SF results obtained using $M_A = 1.03$ GeV, which are too low to reproduce the cross sections from NOMAD [\[48\]](#page-6-5). Owing to their large uncertainties, the T2K CC QE data [\[14,47\]](#page-5-19) cannot discriminate between the two calculations.

Adding the considered CC QE estimates to the cross sections for resonant, nonresonant, and coherent pion production from GENIE, we have calculated the inclusive CC cross sections for carbon shown in Fig. [2.](#page-2-1) The two considered approaches turn out to be in good agreement with the NOMAD data [\[4\],](#page-4-2) collected in the region dominated by pion production.

To compare to the T2K [\[1,2\]](#page-4-0) and SciBooNE [\[3\]](#page-4-1) data, extracted for the hydrocarbon target, we have accounted for the contribution of free protons using the cross sections from GENIE. While the on-axis T2K data point [\[2\]](#page-4-6) does not distinguish the two approaches, the SciBooNE point [\[3\]](#page-4-1) clearly favors the GENIE $+ \nu T$ calculations and the offaxis T2K point [\[1\]](#page-4-0) shows a distinct preference for the effective calculations.

The puzzling difference between the T2K and SciBooNE data—interesting in its own right—has important consequences for neutrino-oscillation studies. We discuss them

FIG. 1. CC QE (a) ν_{μ} and (b) $\bar{\nu}_{\mu}$ cross sections. The results for carbon obtained using GENIE + ν T (dashed lines) and the SF approach with $M_A = 1.2$ GeV (solid line) are compared with the carbon data reported by the MiniBooNE [\[7,8\]](#page-4-5) and NOMAD [\[9\]](#page-5-0) Collaborations and the hydrocarbon data extracted from the MINERvA [\[21,22\]](#page-5-7) and T2K [\[14,47\]](#page-5-19) experiments. For comparison, the MiniBooNE data divided by 1.2 are also shown.

for the ν_{μ} and $\bar{\nu}_{\mu}$ disappearance analysis of an experiment using an off-axis (2.5°) beam peaked at ∼600 MeV [\[18\]](#page-5-4). The near (far) detector with a fiducial mass of of 1.0 (22.5) kton is located at a distance of 1 (295) km from the neutrino source.

We adopt the kinematic method of energy reconstruction, applying it to all event types as in Ref. [\[24\]](#page-5-9). As neutralcurrent background is expected not to play an important role, we do not take it into account. Our analysis employs GLoBES [\[49](#page-6-6)–51] and is based on ∼6000 unoscillated events with reconstructed energies between 0.3 and 1.7 GeV, in both the neutrino and antineutrino modes. The oscillation-parameter values assumed as the true ones are detailed in Table [I](#page-3-0). Implementing χ^2 , we apply a 20% systematic uncertainty of the shape (normalization), bin-to-bin uncorrelated (correlated).

In our analysis, the true event rates are simulated using the GENIE + ν T calculations, and the fitted rates are obtained for both considered approaches over a range of atmospheric oscillation parameters, θ_{23} and Δm_{31}^2 . Having determined the minimal χ^2 value, $\chi^2_{\text{best-fit}}$, the confidence regions are found from the condition

$$
\Delta \chi^2(\theta_{23}, \Delta m_{31}^2) \equiv \chi^2(\theta_{23}, \Delta m_{31}^2) - \chi^2_{\text{best-fit}} < l,\tag{2}
$$

where $l = 2.30, 6.18,$ and 11.83 for the 1, 2, and 3σ confidence level, respectively.

Before discussing the oscillation results, it is illustrative to compare the reconstructed energy distributions for muon neutrinos and antineutrinos obtained from the $GENIE + \nu T$ and effective calculations. As shown in Fig. [3](#page-3-1), the differences between the two cross-section

FIG. 2. Per-nucleon CC inclusive (a) ν_{μ} and (b) $\bar{\nu}_{\mu}$ cross sections divided by neutrino energy, obtained using the QE contributions of Fig. [1](#page-2-0). The calculations for the carbon target (and for the hydrocarbon target in the inset) are compared with the carbon data extracted from the NOMAD [\[4\]](#page-4-2) experiment and the hydrocarbon flux-averaged measurements reported by the SciBooNE [\[3\]](#page-4-1) and T2K [\[1,2\]](#page-4-0) Collaborations (the central energy values correspond to the mean energy in the detector). Note that antineutrino data are currently unavailable.

TABLE I. The oscillation parameters assumed in the analysis.

Δm_{21}^2 (eV ²) Δm_{31}^2 (eV ²) θ_{12} (°) θ_{23} (°) θ_{13} (°) δ		
7.50×10^{-5} 2.46×10^{-3} 33.48 42.30 8.50 0.0		

estimates translate into differences between the oscillated event rates in the far detector, with the discrepancies being particularly severe in the case of antineutrinos.

In addition to the total event numbers, the two approaches yield clearly different distributions of reconstructed energy, as shown in Fig. [4](#page-3-2) for the true energy $E_{\nu} = 0.6$ GeV and in the Supplemental Material for $0.2 \le$ $E_v \le 2.0$ GeV [\[52\].](#page-6-7) While in the effective calculations, $2p2h$ processes enhance the low-energy tails of the distributions, in the GENIE + ν T approach, they also produce additional bumps, corresponding to the reconstructed energy ∼0.4 GeV at the kinematics of Fig. [4.](#page-3-2) In the antineutrino case, for $E_v \lesssim 1.4$ GeV the strength of these $2p2h$ bumps turns out to be larger than that of the QE ones, located at $E_{\nu}^{\text{rec}} \simeq E_{\nu}$. The observed differences in the reconstructed energy distributions have important consequences for the oscillation analysis.

The obtained confidence regions are shown in Fig. [5](#page-4-7). The shaded areas represent the results for the GENIE $+ \nu T$ fitted rates, and the solid lines correspond to the fitted rates from the effective calculations. The high values of $\chi^2_{\text{best-fit}}$ per degree of freedom, given in Fig. [5,](#page-4-7) clearly indicate that the differences between the two considered approaches are too large to be neglected in a precise oscillation analysis. We have verified that this observation holds true even when the normalization of the QE event sample, with any number of nucleons, is treated as arbitrary. Therefore, the observed effect can be traced back to the shape discrepancies displayed in Figs. [1](#page-2-0) and [4](#page-3-2), which appear to be especially large for antineutrinos. In particular, as for antineutrinos in the relevant E_{ν} region the reconstructed energy distributions in the effective and GENIE $+ \nu$ T approaches are peaked at different values, the extracted Δm_{31}^2 is subject to larger bias for antineutrinos than for neutrinos.

In summary, we have studied the impact of discrepancies between experimental cross sections on neutrinooscillation analysis, adopting the kinematic method of energy reconstruction. We have compared two data-driven approaches focusing on the 1-GeV energy region and

FIG. 3. Distribution of CC (a) ν_{μ} and (b) $\bar{\nu}_{\mu}$ events in the far detector as a function of the reconstructed energy, obtained within the GENIE + ν T and effective calculations. For comparison, we also show the GENIE + ν T results with the unoscillated QE event rates rescaled to those of the effective calculations.

FIG. 4. Reconstructed energy distributions of CC QE (a) ν_{μ} and (b) $\bar{\nu}_{\mu}$ events with any number of nucleons calculated at $E_{\nu} = 0.6$ GeV. The dashed (solid) lines represent the results obtained using the GENIE + ν T (effective) approach.

FIG. 5. Confidence regions in the $(\theta_{23}, \Delta m_{31}^2)$ plane for the true (a) ν_μ and (b) $\bar{\nu}_\mu$ event rates from GENIE + ν T at the 1, 2 and 3 σ C.L. The shaded areas (solid lines) correspond to the fitted rates from the GENIE $+ \nu T$ (effective) calculations.

shown that the differences between them have a sizable effect on the resulting oscillation parameters, especially in the antineutrino channel.

In view of these findings, improving the precision of the neutrino and antineutrino cross sections will be of great importance for future oscillation studies. Such progress will require new experimental data for energies ∼1 GeV, as well as an improvement in the understanding of systematic uncertainties, which would allow the tensions between existing measurements to be significantly alleviated.

Because the description of final-state hadrons involves larger uncertainties than those associated with leptons, the conclusions of this article are expected to also apply to the calorimetric method of energy reconstruction and are, therefore, relevant to the next generation of long-baseline oscillation measurements, such as the Deep Underground Neutrino Experiment [\[26\]](#page-5-20), aimed at determining the charge-parity violating phase and at verification of the three-neutrino paradigm.

ACKNOWLEDGMENTS

We would like to express our gratitude to Chun-Min Jen for generating the events used in this analysis and for extracting the cross sections from GENIE. E. V. is indebted to Davide Meloni for many useful discussions. Preparing the manuscript, we also benefited from the comments of Pilar Coloma and Steve Dytman. The work of A. M. A. and C. M. was supported by the National Science Foundation under Grant No. PHY-1352106.
