(Received 8 May 2019; revised manuscript received 24 June 2019; accepted 31 January 2020; published 18 February 2020)

We investigate the impact of attractive-repulsive interaction in networks of limit cycle oscillators. Mainly we focus on the design principle for generating an antiphase state between adjacent nodes in a complex network. We establish that a partial negative control throughout the branches of a spanning tree inside the positively coupled limit cycle oscillators works efficiently well in comparison with randomly chosen negative links to establish zero frustration (antiphase synchronization) in bipartite graphs. Based on the emergence of zero frustration, we develop a universal $0-\pi$ rule to understand the antiphase synchronization in a bipartite graph. Further, this rule is used to construct a nonbipartite graph for a given nonzero frustrated value. We finally show the generality of $0-\pi$ rule by implementing it in arbitrary undirected nonbipartite graphs of attractive-repulsively coupled limit cycle oscillators and successfully calculate the nonzero frustration value, which matches with numerical data. The validation of the rule is checked through the bifurcation analysis of small networks. Our work may unveil the underlying mechanism of several synchronization phenomena that exist in a network of oscillators having a mixed type of coupling.

I. INTRODUCTION

A tug-of-war between attractive and repulsive coupling can establish complex behavior $[1-9]$ in a large class of coupled oscillators. For instance, it can create resonance in a network of spinlike dynamical variables [\[10\]](#page-8-0) or help in the entertainment process for biological networks [\[11–13\]](#page-8-0). A careful selection of negative links of attractively coupled oscillatory system can systematically establish homogeneous or inhomogeneous solution $[14–19]$ or may generate diverse chimera states ranging from clustered death to amplitude chimera states [\[20](#page-8-0)[–23\]](#page-9-0). On the other hand, a signed (mixture of attractive-repulsive coupling) and balanced graph of phase oscillators may uncover the underlying structure of the networks [\[24\]](#page-9-0) on the basis of synchronous phase clusters. Identification of critical nodes as well as graph partitioning in real ecological signed graphs can also be recognized from the reorganization of synchronized clusters $[25,26]$. Also, the network of Kuramoto dynamics [\[27\]](#page-9-0) having phase lag [\[28\]](#page-9-0) in identical frequency environment can split the stationary phases into several clusters [\[29\]](#page-9-0) revealing the underlying symmetry of the given network. On the other hand, the inhibition or delayed feedback naturally suppresses (controls) the complex synchronization pattern [\[30–34\]](#page-9-0) or generates multistability [\[35\]](#page-9-0). Besides, rewiring links in a network may reveal antiphase states between the adjacent nodes in repulsively coupled phase oscillators [\[36,37\]](#page-9-0).

However, the emergence of antiphase state [\[38\]](#page-9-0) between adjacent nodes in attractive-repulsively coupled complex networks is not well explored till now to the best of our knowledge. Here, we would like to understand the suitable characteristics of a network, for which the adjacent nodes of that network can settle themselves into an antiphase state in the presence of a tiny fraction of repulsive links of a group of attractively coupled limit cycle oscillators and in absence of such attribute, the network cannot reveal antiphase states.

The manifestation of antiphase synchronization has been profoundly studied in various physical systems, from both numerical and experimental [\[39,40\]](#page-9-0) points of view. One of the premier specimens, to observe such an emergent phenomenon, is the cortical neural network [\[41,42\]](#page-9-0). Antiphase patterns have been found there too. Recently, antiphase collective synchronization [\[43\]](#page-9-0) has been observed among two pairs of electrochemical oscillators with strong internal and weak external coupling. All these inspections attest to the necessity of studying antiphase synchronization in coupled complex networks. In this paper, based on the emergence of antiphase synchronization, we would like to classify the entire class of networks into two distinct groups of classes, one in which adjacent nodes can exhibit such antiphase patterns, while the oscillators of the other types of networks fail to rearrange into such antiphase formation.

The essential term to quantify the antiphase synchronization between two neighboring nodes *i* and *j* is to calculate the local frustration between them and which is expressed as $f_{\text{local}}^{ij} = C_{ij} [1 + \cos(\phi^i - \phi^j)]$, where C_{ij} is the elements of the symmetric binary connectivity matrix C , i is an arbitrary node in the network, *j* is the neighbor of *i* and ϕ^{i} is the intrinsic phase of the *i*th node. Here, $0 \n\t\le f_{\text{local}}^{ij} \le 2$. *L* is the total number of links, then $F = \langle \frac{1}{L} \sum_{i < j} f_{local}^{ij} \rangle_t$ represents the total frustration in the entire network and it accumulates all f_{local}^{ij} present in the network. Here $\langle \cdots \rangle_t$ stands for time average. $F = 0$, i.e., nonfrustrated system implies the antiphase states in the entire networks and thus, each pair of adjacent nodes will follow antiphase $(|\phi^i - \phi^j| = \pi)$ states between them and the dynamics of the system will no longer be able to stretch along links beyond the phase differences of π . $F = 2$ signifies in-phase synchrony in the network as $|\phi^{i} - \phi^{j}| = 0$. The nonzero value of *F* reflects frustration nature $[4,22,36,37,44-46]$ $[4,22,36,37,44-46]$ of the system, in which most of the adjacent nodes will be out of phase to each other, as at least a few links will be squeezed to a phase difference less than π and frustrate the simultaneous minimization of the energy of all the interacting pairs of subunits of a system. Treating *F* as the elastic potential energy [\[4\]](#page-8-0) contained within the connected network, *F* captures how squeezed a link is.

We examine here how attractive-repulsively coupled oscillators can impact *F* in a complex network. We show here that a few number of negative links may induce zero frustration in a bipartite graph. Therefore, the main focus of this paper is to answer the following key questions: (i) Which links are crucial to obtain antiphase states $(F = 0)$ in a bipartite graph? More precisely, we would like to identify which positive links should be replaced with negative ones for faster decay of *F* from 2 to 0? And, (ii) Can we design a nonbipartite graph that can give us as our expected desired *F* ($F \neq 0$)?

The rest of the paper is arranged as follows. In Sec. II, we discuss the model description and how the attractive and repulsive links are chosen in the considered network. In Sec. III, we show the efficient arrangement of negative links in the bipartite graph of attractively coupled limit cycle oscillators. The arrangement can produce zero frustration easily. Sections [IV](#page-4-0) and [V](#page-5-0) analyze the bifurcation of the oscillatory nodes and establish a $0-\pi$ rule to understand the zero frustration in bipartite graph. In Sec. [VI,](#page-5-0) nonbipartite graphs (based on 0 - π rule) are constructed for desired nonzero *F*. Finally, we show that our proposed rule can be implemented for any nonbipartite graph and we can easily calculate *F* for any arbitrarily chosen graph of limit cycle in presence of attractive-repulsive coupling in Sec. [VII.](#page-6-0) Lastly, we conclude our findings in Sec. [VIII.](#page-7-0)

II. MATHEMATICAL MODEL

We start with *d*-dimensional oscillatory agent. The dynamics of each agent is used over the top of each node of the network. The evaluation of the *i*th agent is captured by

$$
\dot{\mathbf{x}}^{i} = \psi(\mathbf{x}^{i}) + K_{A} \sum_{j=1}^{N} A_{ij} H(\mathbf{x}^{i}, \mathbf{x}^{j})
$$

$$
+ K_{R} \sum_{j=1}^{N} B_{ij} H(\mathbf{x}^{i}, \mathbf{x}^{j}), i = 1, 2, ..., N \qquad (1)
$$

with the vector $\mathbf{x}^{i}(t)$ is the state variable, $\psi : \mathbb{R}^{d} \to \mathbb{R}^{d}$ given by the system's intrinsic dynamics, the attracting coupling strength $K_A > 0$ ensures in-phase synchronization for a certain threshold, and the repulsive (negative) strength K_R tries to push the entire system out of phase synchronization by disturbing the in-phase synchronization manifold. The function $H(\mathbf{x}^i, \mathbf{x}^j)$ is the vector coupling representing diffusive type, i.e., $H(\mathbf{x}^i, \mathbf{x}^j) = (\mathbf{x}^j - \mathbf{x}^i)$. Here A_{ij} and B_{ij} are the binary elements encoding the information of the underlying attractive and repulsive connectivity patterns among the dynamical agents. The total number of links of the entire network (matrix *C*) is the sum of links encoded in the matrices *A* and *B*.

As a paradigmatic model, we choose Landau-Stuart (LS) oscillators where the state dynamics of each limit cycle oscillators is represented by

$$
\psi(\mathbf{x}^{i}) = \begin{pmatrix} [1 - (x^{i^{2}} + y^{i^{2}})]x^{i} - \omega^{i}y^{i} \\ [1 - (x^{i^{2}} + y^{i^{2}})]y^{i} + \omega^{i}x^{i} \end{pmatrix},
$$
(2)

where $H(\mathbf{x}^i, \mathbf{x}^j) = [x^j - x^i, 0]^T$ is the coupling function and $\omega = \omega^i = 3$ is identical intrinsic frequency of each node. The intrinsic and instantaneous phase of each node is calculated by $\tan \phi^i = \frac{y^i}{x^i}$.

To address the first question raised in Sec. [I,](#page-0-0) we start with a small network [Fig. $1(a)$ or $1(d)$], having the size $N = 12$ nodes and total links $L = 19$. To test the impact of attractive-repulsive interactions, we introduce negative coupling $(K_R < 0)$ on randomly chosen $N_L = 11$ (approximately 60% of the total links) links shown by red color in Fig. [1\(a\).](#page-2-0) The remaining $L - N_L$ links (black arcs) are coupled through weak positive interaction *KA*.

If we introduce positive strength over all links, the coupled oscillators will oscillate with a common rhythm (not shown here) by adjusting themselves with common phase even with identical amplitude. However, if we replace $N_L (= 11)$ attractive links by negative strength ($K_R = -0.1$) (red links), the coherent phase distribution is scattered and out of phase emerges in the system. For instance, the nodes connected for an arbitrarily chosen link (link between nodes 4 and 7) reflects the lag synchronization with slightly distorted amplitude fluctuations between them shown in Fig. [1\(b\).](#page-2-0) Keeping the entire links structure fixed, if we increase the negative strength $K_R = -4$, the population reaches to steady states [Fig. $1(c)$] and it neither shows in-phase nor antiphase synchronization as all the emerging fixed points (FPs) are either in the third or fourth quadrant of the phase space. The phase differences between the existing links are not in the difference of π . Therefore, F gives a positive nonzero value 0.3 for both cases [Figs. $1(b)$ and $1(c)$]. This signifies that the links are either in in-phase mode or out-of-phase mode leading to the existence of at least few frustrated links with $f_{\text{local}}^{ij} > 0$ and hence, weak frustration (*F* > 0) in the entire network. A distinct and qualitatively different feature $(F = 0)$ appears for another arrangement of negative links [Fig. $1(d)$] in red color], in which any arbitrary node stays in antiphase with its nearest neighbor either in a lower negative coupling [Fig. [1\(e\)](#page-2-0) shown for the node 4 and its neighbor 7] or in higher negative strength [Fig. $1(f)$]. In the higher negative strength, the FPs stay opposite to each other in the phase space (second and fourth quadrants). The obtained results give us a hint that proper choices of negative links in the network is essential for constructing a network with zero frustration, i.e., an emergence of antiphase synchronization $(f_{local}^{ij} = 0)$ between two adjacent nodes, an interesting impact of negative links in positively coupled networks never explored before to the best of our knowledge. The objective of this paper is to link the network structure with the dynamical process such a way that we can understand the underlying mechanism of obtaining zero $(F = 0)$ and nonzero frustrations $(F > 0)$ of positive-negatively coupled environment of limit cycle oscillators with fixed point and oscillation states.

III. EFFICIENT ARRANGEMENT OF REPULSIVE LINKS FOR OBTAINING ANTIPHASE $(F = 0)$ IN A **BIPARTITE GRAPH**

To proceed further, we first focus on our network described in Fig. [1.](#page-2-0) The underlying network is bipartite by nature. A

FIG. 1. Impact of different arrangement of repulsive links. A network with $N = 12$ nodes and $L = 19$ links are considered in (a) and (d) where the black lines are attractive links, the red (gray) ones are the repulsively coupled $(N_L = 11)$ links. The underlying architecture remains same for both. Due to different choices of repulsive links, same *KA* and *KR* lead to different scenarios shown in (b), where node 4 (time series in blue line) and 7 (time series in red line) are slightly lagged to each other, however they are opposite to each other (antiphase) shown in (e). For more higher coupling, the entire network reaches to inhomogeneous steady states portrayed in (c) and (f). In the cases of (e) and (f), the frustration index *F* is zero but, $F > 0.3$ for (b) and (c). $K_A = 0.001$ and $K_R = -0.1$ are chosen for (b) and (e). $K_A = 0.001$ and $K_R = -4$ are taken for (c) and (f).

graph *G* is called bipartite if its vertex set V can be decomposed into two disjoint subsets *U* and *V* such that every link in *G* joins a node in *U* with a node in *V*, i.e., $U \cap V = \phi$, where ϕ is the null set and $U \cup V = V$. The nodes of the network described in Fig. 1 can be split into two disjoint sets: $U = \{1, 3, 4, 5, 8, 10, 11\}$ and $V = \{2, 6, 7, 9, 12\}$. The comparative observation in Fig. 1 helps us to conclude that repulsive links, chosen in the Fig. $1(d)$, are somehow more influential (effective) than other choices of random repulsive links [Fig. $1(a)$]. We also observe that the repulsive links, chosen in Fig. $1(d)$, is the minimally connected subgraph, which touches all the nodes manifested as a spanning tree in the given network. However, the randomly chosen links in Fig. $1(a)$ cannot form a spanning tree (as the links fail to cover all the nodes) and *F* never reaches to the minimum value $F \approx 0$.

We aim here to find the partial negative control in a bipartite graph of limit cycle oscillators to obtain $F = 0$ either in oscillatory regime or in steady-state regime. The signature that we have gotten from our observed results (cf. Fig. 1), which directs us to use the partial negative control in the bipartite graph with a proper arrangement, i.e., passing the negative links through a spanning tree embedded in the considered graph. Therefore, we hypothesize that finding a spanning tree and passing the negative strength through it gives a faster zero frustration (antiphase state) compared to randomly chosen negative links in a bipartite graph of limit cycle oscillators.

To validate our hypothesis, we start with two bipartite graphs having size $N = 100$ with average degree $\langle k \rangle = 12$ (Net1) and $\langle k \rangle = 6$ (Net2). We strategically select *N* − 1 repulsive links in two different ways: (i) one set of links is chosen through a spanning tree and (ii) other sets of links are chosen randomly. The negative coupling strength (K_R) of each branch in the tree is changed continuously (adiabatically) from 0 to −4. We fix the coupling strength of each attractive link at $K_A = 0.2$. It is clear that the repulsive spanning tree can induce zero frustration [Fig. $2(a)$ with unfilled red circles for Net1 and unfilled black squares for Net2] in the bipartite graphs. However, randomly chosen negative links cannot induce zero frustration [shown in Fig. $2(a)$ with filled red circles (Net1) and filled black squares (Net2)]. The result of getting $F = 0$ in the bipartite network is consistent with previous work [\[37\]](#page-9-0) where an evolutionary process to construct nonfrustrated $(F = 0)$ networks of phase repulsive dynamics for a certain upper limit on the number of edges is designed. On the other hand, in our study, only replacing a certain fraction of attractive links by negative ones can induce such phenomena.

Next, to study the effect of network size *N*, we perform numerical simulations on eight networks ranging from $N =$ 10 to $N = 2 \times 10^3$ shown in Fig. [2\(b\).](#page-3-0) In all cases, calculated *F* through random paths of length $(N - 1)$ give nonzero *F*, whereas if we pass the repulsive coupling through the branches of an underlying spanning tree, the numerically calculated F is always close to zero. This confirms that our

FIG. 2. Comparison of frustration index where links are chosen by randomly and through spanning tree. (a) Two networks (Net1 and Net2) of same size (*N* = 100) are considered. Red and black filled circle are drawn by considering randomly chosen (*N* − 1) links. Impact of negative spanning tree is shown with unfilled circles and squares. (b) Spanning tree creates zero frustration in larger networks. (c) Synchronization order parameters (R, R_U, R_V) as a function of repulsive strength K_R . 50 independent numerical realizations are taken to obtain these observations of (a) and (b). Here $K_A = 0.2$. (d)–(f) Impact of spanning tree in weak coupling. The coupling parameters are set in oscillatory regime and antiphase is clearly established. (d) and (e) limit cycles and time series of *x* arbitrarily chosen nodes from the two disjoint subsets *U* and *V* in red and blue lines, respectively. (f) Antiphase synchronization between x_U and x_V for several arbitrarily chosen nodes. Here, $K_A = 0.01, K_R = -0.1.$

method is performing well even in large complex networks. 50 independent statistical realizations are used to produce the Fig. 2(b). It should be noted that with increasing *N*, the basin of attraction becomes much constricted [\[45\]](#page-9-0) and hence, one should start with suitable initial conditions to enhance the probability of reaching $F = 0$ through repulsive spanning tree. Another important observation of this figure is that the deviation of the calculated *F* through randomly chosen edges of length $(N - 1)$ is comparatively wide for larger *N*, as such dynamics can have multiple inhomogeneous steady states leading to a wide range of *F* values, however, they never reach to zero.

It is clear now that nodes in same subset (either *U* or *V*) will be in in-phase states, and they will be antiphase to each other, which is further confirmed by the order parameters $Re^{i\psi} = \frac{1}{N} \sum_{j=1}^{N} e^{i\phi^{j}}$, $R_{U}e^{i\psi^{j}} = \frac{1}{N_{1}} \sum_{l \in U} e^{i\phi^{l}}$, and $R_{V}e^{i\psi^{m}} =$ $\frac{1}{N_2} \sum_{k \in V} e^{i\phi^k}$, where ψ , ψ' , ψ'' are the common phases appear in the time of unison and R , R_U , R_V are the degree of synchronization of the whole set $V = U \cup V, U$, and *V*, respectively. Here, the number of nodes in the subsets *U* and *V* are *N*¹ and N_2 , respectively, and $N_1 + N_2 = N$. In Fig. 2(c) (for the network Net1), we observe that the order parameter in each subsets will follow the in-phase solution ($R_U \approx 1, R_V \approx 1$) at $K_R = -4.0$, where, as the global order parameter *R* eventually reaches to zero, as phases of the two subsets follow antiphase to each other. This feature ($R \approx 0$) is consistent with $F \approx 0$. Note that the emergence of antiphase between adjacent nodes is calculated through the stationary phases obtained from steady states as it stabilizes the systems to stable fixed points. These fixed points are called inhomogeneous steady states or oscillation death [\[15,](#page-8-0)[47–49\]](#page-9-0). These coupling-dependent fixed points manifest oscillation quenching by breaking the system's symmetry. Interestingly, the spanning tree can do the same effect $(F$ and R will be zero) in limit cycle regime considered at lower negative strength $K_R = -0.1$, when $K_A =$ 0.01. We consider a sparse diluted bipartite graph having size $N = 100$ with average degree $\langle k \rangle = 3$. Trajectories oscillating in the limit cycle regime are depicted with a phase space diagram in Fig. $2(d)$. In Fig. $2(e)$, few time series are randomly chosen from the two subsets *U* (red color) and *V* (blue). The antiphase synchronization manifold is confirmed from Fig. 2(f).

It is also clear that a network having arbitrarily chosen degree sequences cannot always lead us into antiphase state $(F \approx 0)$ as the several graphs will not have bipartite structure. The nonbipartite graph contains odd cycles and thus, the set of all vertices V can not be partitioned into two disjoint sets, i.e., the nodes within a subset can be connected to each other reflecting the in-phase solution ($f_{\text{local}}^{ij} > 0$). Therefore, *F* will be deviated from the global minimum zero value. For instance,

FIG. 3. Ring network of four nodes. Repulsive links are shown by red arcs and the black edge represents attractive interaction. Red links form a spanning tree in the given graph (ring). Figure is drawn using the software Gephi [\[51\]](#page-9-0).

if one considers a triangle, which is a nonbipartite graph and assigns all links as negative, the total *F* can never be zero [\[37\]](#page-9-0). Let us assume the cardinality of the sets are, respectively, $|U| = N_1$ and $|V| = N_2$. Hence, the maximum number of possible links is N_1N_2 , so that the network remains bipartite. Using $N_1 + N_2 = N$, we get $g(N_1) = N_1(N - N_1)$, which is maximized at $N_1 = \frac{N}{2}$ and the maximum value of *g* is $\frac{N^2}{4}$. So, any network can not be rearranged in a bipartite configuration, because at most $\frac{N^2}{4}$ links are contained by a bipartite graph with N nodes. Therefore, the previous observation $[37]$ in the restriction on the number of total edges in a network having zero frustration is due to the breaking of bipartite structure of a network. A natural question appears to be what will be the impact of negative spanning tree in a nonbipartite graph of limit cycle oscillators? Of course, the presence of odd-cycles in a nonbipartite graph will resist to set *F* to zero. Although we will show (in Secs. [VI](#page-5-0) and [VII\)](#page-5-0) that we can efficiently calculate the nonzero value of F for any arbitrarily chosen nonbipartite graph and easily construct sparse nonbipartite graph for any nonzero desired frustration value $(F > 0)$.

We have avoided multistability (emergence of coexisting fixed points) [\[35,36,50\]](#page-9-0) by adiabatically increasing the negative coupling strength for all numerical calculations. A connected graph can have more than one spanning tree, but all spanning trees are connected by $N - 1$ edges and we would like to explore the contribution of different repulsive trees in near future. To understand the stationary phase distributions of the steady states of LS limit cycle oscillators, we perform the bifurcation analysis of simple bipartite graph in the next section. For instance, Fig. $1(f)$ confirms that the entire network (a bipartite graph) reaches to steady states for strong negative coupling and follows some symmetric condition as the most of the fixed points are situated either in second or fourth quadrant and the frustration index F is zero. In the next section, we describe the bifurcation nature for a small bipartite graph, which will reflect why the nodes are in two opposite quadrants in the phase space.

IV. BIFURCATION ANALYSIS IN A SMALL BIPARTITE GRAPH

We consider a simple even cycle ring network with four nodes (Fig. 3). A randomly chosen spanning tree inside

FIG. 4. Bifurcation diagram of $N = 4$ coupled Landau-Stuart oscillators (using the network drawn in Fig. 3) with $K_A = 0.2$ and $\omega = 3.0$. Here, red thick lines: stable fixed points; dashed black lines: unstable fixed points; *SN*: saddle-node bifurcation.

the graph is shown by red arcs. We set the attractive coupling strength at $K_A = 0.2$ and negative strength at $K_R =$ −4.0. These four coupled LS oscillators [Eq. [\(1\)](#page-1-0)] have five real fixed points $(FP_i : i = 1, 2, ..., 5)$ in which two of the fixed points (say FP_1 : $x^1 = -x^4 = -3.827$, $y^1 =$ $-y^4 = -0.8033$, $x^2 = -x^3 = 2.797$, $y^2 = -y^3 = 1.057$, and *FP*₂: $x^1 = -x^4 = 3.827$, $y^1 = -y^4 = 0.8033$, $x^2 = -x^3 =$ $-2.797, y^2 = -y^3 = -1.057$ are stable nodes whereas the other three fixed points are unstable foci. We are only interested to study the behavior of these two stable nodes. Noticeably, we observe that the derived stable fixed points *FP*¹ and *FP*₂ maintain a relation in the form $x^1 = -x^4$, $y^1 = -y^4$ and $x^2 = -x^3$, $y^2 = -y^3$. Also for *FP*₁, (x^1, y^1) and (x^3, y^3) are in the same quadrant (third quadrant in the phase space) whereas (x^2, y^2) and (x^4, y^4) stay in the first quadrant. This feature is also applicable for FP_2 where (x^1, y^1) and (x^3, y^3) are in the first quadrant and the rest are in the third quadrant. Clearly, the nodes that are disconnected, i.e., not neighbors to each other, lie within same quadrant. This unique and interesting observation is consistent with the graph, as the nodes are split into two disjoint sets: $U = \{1, 3\}$ and $V = \{2, 4\}$. Note that, the system may undergo multistability, i.e., may change the value of x^i . However, the repulsive tree solely determine the sign of the stable fixed points. For instance (for a given initial condition) if one gets x^1 and y^1 as positive (negative), x^3 and *y*³ will also be positive (negative). The same features occur for x^2 , y^2 and x^4 , y^4 . This observation is also demonstrated with the help of the bifurcation diagram Fig. 4. Numerical bifurcation diagram of Fig. 4 using XPPAUT [\[52\]](#page-9-0) yields that the stable nodes coexist, further if we increase K_R , the node comes closer to unstable fixed point and eventually annihilate around $K_R \approx -2.0$ through saddle-node bifurcation. In the next section, we calculate the stationary phases of all the nodes. Using the unique appearance of fixed points

FIG. 5. Regular bipartite graph with six nodes. $K_{3,3}$ with five repulsive links (red arcs) and 4 attractive links (black arcs). Here $U = \{1, 2, 3\}$ and $V = \{4, 5, 6\}$. We assign 0 phase for *U* set and π for *V* set (or vice versa).

in the phase space, we establish a $0-\pi$ rule, which further confirms the emergence of antiphase state among neighboring nodes (i.e., zero frustration) for any bipartite graph.

V. 0-*π* **RULE TO DETERMINE THE ZERO FRUSTRATION IN BIPARTITE GRAPH**

We calculate the stationary phase value $(\tan \theta^i = \frac{y^i}{x^i})$ of each node in the given network (Fig. [3\)](#page-4-0) at $K_R = -4.0$. The stationary phase values up to four decimal places are: θ^1 = $-2.9347, \theta^2 = 0.3613, \theta^3 = -2.7803, \text{ and } \theta^4 = 0.2069 \text{ of }$ the nodes 1, 2, 3, and 4, respectively. Though these phase values are not unique (can be altered for different initial conditions as noted in the bifurcation diagram Fig. [4\)](#page-4-0), but one significant property is observed: the modulus of phase difference between two nodes (if link exists) is always π for all the links, therefore the frustration index *F* will be zero irrespective of that of the initial conditions. This will happen when $|\theta^i - \theta^j| \simeq \pi$ for $\theta^i \in U = \{1, 3\}$ and $\theta^j \in V = \{2, 4\}$, where *U* and *V* are disjoint sets $(U \cap V = \phi)$. We notice that this inspection helps us to apply a change of origin in the (r, θ) plane without changing the directions of the axes. For instance, here the origin $(0,0)$ can be translated to $(0, -0.3612)$ so that in the new transformed coordinate system, we can acquire π as the phase of each nodes of *U* and phase 0 is set for the vertices of *V*. Similarly, for the utility graph $K_{3,3}$ (Fig. 5), we find that the final phase values for the chosen spanning repulsive tree are $\theta^1 = 0.1445$, $\theta^2 = 0.3401$, $\theta^3 =$ 0.3401, $\theta^4 = -2.8015$, $\theta^5 = -2.8015$, and $\theta^6 = -2.9971$, which again imply $|\theta^i - \theta^j| \simeq \pi$ for $\theta^i \in U = \{1, 2, 3\}$ and $\theta^{j} \in V = \{4, 5, 6\}$ eventually determines *F* as zero. Thus, with a suitable phase shifting, we can allocate π as the phase of each nodes of *U* and phase 0 is set for the vertices of *V* (or vice versa). This whole observation (bifurcation analysis and obtained θ values for each node) enables us to establish a $0-\pi$ rule for any arbitrary bipartite graph to predict *F* without investigating the local dynamical units at higher negative strength. Note that, this rule is also verified for Figs. [1\(f\),](#page-2-0) [2\(b\),](#page-3-0) and $2(d)$ (for sufficient repulsive strength in three bipartite graphs) in which any arbitrary node will stay in antiphase with respect to its nearest neighbors. In this context, the local frustration f_{local}^{ij} will be zero as $|\theta^j - \theta^i| = \pi$ which further implies $F = 0$.

VI. DESIGNING A NONBIPARTITE NETWORK FOR DESIRED FRUSTRATION

The unique feature of *F* having zero value for bipartite graph elucidates us to formulate a design principle of constructing a nonbipartite graph having desired (given) frustration *F*desired for a given tree. As discussed above, the disjoint nodes of a spanning tree will be distributed with two phase values: either 0 (say for *U*) or π (say for *V*). Now, the additional attractive link randomly attached to any two nodes of the tree may give us two values of local frustration: zero, if both of them have different phases to each other (two nodes are not chosen from the same set, i.e., one is chosen from *U* and the other one is from *V*) or 2, if two nodes either in zero phase or in π phase (nodes are chosen from the same set, i.e., either both are from *U* or from *V*). Assume, we have a spanning tree of *N* nodes with negative links and we would like to construct a network such that we will eventually reach a desired frustration (F_{desired}) index. For this, suppose we have to add *m* (say) number of minimum links such that we can reach *F*_{desired}. Therefore, the underline condition is $F_{\text{desired}} \approx \frac{2m}{L}$. Here *L* is the total number of links in the network, i.e., $m +$ $(N - 1) = m + N_L = L$. The number 2 appears in numerator due to the contribution of positive links in the local frustration term in the time of network construction. In the Appendix, we describe each step in details for the construction of our network. Note that, the algorithm is based on the following hypothesis that a spanning tree will have two phase values: 0 for *U* and π for *V* or vice versa and link will be added between two nodes if and only if their phase difference is zero. Based on this hypothesis, we have added links (between the nodes in the tree) continuously unless we reach our desired *F*. The required number of attractive links (*m*) for a given *F* are shown in the Fig. 6. The *F*_{desired} of the newly constructed network perfectly matches with the numerically calculated *F* by considering LS dynamics over the top of the same network (shown with yellow circles). In conclusion, we can state that for a given tree one can easily construct a network by adding

FIG. 6. Network construction from a given spanning tree with **F**_{desired}. Red line represents the analytical curve as per our proposed mechanism (based on $0-\pi$ proposition) for network construction with the help of given *F* and a given spanning tree of length $N - 1 =$ 99. Yellow circles are the verification by assigning Landau-Stuart oscillators as the local unit dynamics on the top of our constructed network.

few edges, which can give us our desired frustration index *F*. The approach is simple and it creates a little dense network from the highly diluted graph (a tree only) to shift the *F* value from zero to a desired one. Finally, we obtain the relation between *F*desired and *m* as follows:

$$
m = \left\lceil \frac{(N-1)F_{\text{desired}}}{2 - F_{\text{desired}}}\right\rceil, \quad 0.0 \le F_{\text{desired}} < 2.0. \tag{3}
$$

By suitable isometric translation operator in the Euclidean space, one can reach $XY = C^2$, where $X = 2 - F_{\text{desired}}$, $Y =$ $m + (N - 1)$, and $C^2 = 2(N - 1)$. It is clear that *m* and F_{desired} follow a hyperbolic growth (for a given *N*) to each other, which is clear from the Fig. [6.](#page-5-0) Note that, we need to add more number of attractive links to obtain higher F_{desired} and our algorithm always predicts the lower most *m* for a desired *F*. One can obtain exact in-phase synchronization, i.e., $(F = 2)$, the network needs significantly large number of positive links (*m*) to completely diminish the effect of negative strength connected through the tree.

However, our algorithm creates a strong restriction on the upper bound of *F* in a network of *N* oscillators. If *N* number of nodes connected in a negative spanning tree, then we can add at most 2 $\binom{N/2}{2}$ number of attractive links. The reason is that a bipartite graph will have maximum $\frac{N^2}{4}$ links if the disjoint sets are equally divided, which is discussed earlier. This information further restricts on the upper bound of F_{desired} . For instance, $m = 2\binom{N/2}{2} = 2450$ number of attractive links can be added as per our algorithm for any network of $N = 100$ oscillators. Hence, maximum $F_{\text{desired}} = \frac{2m}{m + (N-1)}$ $4\binom{N/2}{2}$ $\frac{4(\frac{1}{2})}{2(\frac{N/2}{2})+(N-1)} \simeq 1.92$ can be obtained. In fact, this is the largest upper bound of *F*desired with the presence of repulsive spanning tree, as one can add more links $\left[2\binom{N/2}{2}\right]$ by connecting two disjoint sets *U* and *V* , which are in antiphase among themselves. Therefore, these additional edges do not contribute in f_{local}^{ij} (= 0), but those links increase *L* and consequently, reduce F . As a conclusion, we can never reach to complete in-phase synchronization, i.e., $F_{\text{desired}} = 2$ as our analytical expression given in Eq. (3) has singularity at $F_{\text{desired}} = 2$.

VII. CALCULATION OF *F* **FOR ARBITRARY NETWORK**

The constructed nonbipartite graph described in the last section has two types of links: repulsive links in the spanning tree contribute zero in the frustration index *F*, and the *m* attractive links (edges within the same set U or V) only contribute on f_{local}^{ij} . However, an arbitrary chosen graph [e.g., networks used in Fig. $2(a)$] will also have links, which may not contribute in the local frustration index f_{local}^{ij} as those additional links connect random nodes between the subsets *U* and *V* . The maximum number of these types of links will be $\frac{N^2}{4} - (N - 1)$, i.e., the difference between the maximum number of bipartite links possible in the network and a spanning tree, which is a part of that bipartite graph. However, these inactive links may create multistability [\[50\]](#page-9-0) in $0 - \pi$ states of the nodes and may perturb the value of f_{local}^{ij} and hence changes the value of *F*. To test our $0-\pi$ proposition in the considerably dense networks, we have designed several small graphs of size 6. We also check how different spanning trees as repulsive links work inside a graph.

We start with four different networks of six nodes with total number of links: (i) 12 links (first column), (ii) 10 links (second column), (iii) 9 links (third column) and (iv) 7 links (fourth column) in Fig. [7.](#page-7-0) We have identified two separate spanning trees for each network with different links. The branches of spanning trees for each network are shown with red arcs and the attractive links in black arcs. Each of the spanning trees will have $N - 1 = 5$ links irrespective of the variation of link density. However, the same network may reveal different *F*, which solely depends on the choice of spanning tree and its attractive counterpart.

For instance, (i) Figs. $7(a)$ and $7(b)$ have 12 links in which Fig. $7(b)$ gives lesser frustrated index ($F = 0.66$) than the other choice of a spanning tree shown in Fig. $7(a)$ in which $F = 1.2$. The same type of features is revealed for $L = 10$ shown in Figs. $7(c)$ and $7(d)$. Two trees are generated and a comparison reflects that *F* becomes lesser for a spanning that possess larger diameter. We would like to explore the impact of different trees in detail for a large network in the near future. We have also used more diluted graphs where *L* = 9 [Figs. [7\(e\)](#page-7-0) and [7\(f\)\]](#page-7-0) and *L* = 7 [Figs. [7\(g\)](#page-7-0) and [7\(h\)\]](#page-7-0). Next, we calculate the frustration value of the entire network utilizing the 0- π rule mentioned above. As we have shown, a network can reveal zero frustration if and only if the network is bipartite and a spanning tree inside the graph is required to pass the negative signals adiabatically. We assume here that the underlined tree (which itself is bipartite) will always lead to zero frustration. For instance, in the small graph considered in Fig. $7(a)$, we assign the local θ values (through the considered tree shown by red lines) on the vertices as follows: $V^1 = 0, V^2 = \pi, V^3 = \pi, V^4 =$ π , $V^5 = \pi$, and $V^6 = \pi$. Therefore, the frustration of the tree will be zero, which can be calculated by accumulating all the local (link) frustration values $f^{1,6} + f^{1,2} + f^{1,3} + f^{1,4} +$ $f^{1,5} = 0$. Based on this assumption, the total frustration in the entire network that appears from the sole contribution of attractive links is $F = \frac{f^{2,6} + f^{5,2} + f^{5,3} + f^{5,4} + f^{2,3} + f^{5,6}}{12} = \frac{2+2+2+2+2+2+2}{2} \sim 1.1666$ In a similar manner we calculate $\frac{2+2+2+2+2+2+2}{12} \simeq 1.1666$. In a similar manner, we calculate here the total frustration (from the attractive links) of the graph represented in Fig. [7\(b\)](#page-7-0) by setting the θ values of the vertices of the spanning trees $V^1 = 0$, $V^2 = \pi$, $V^3 = 0$, $V^4 =$ π , $V^5 = 0$, $V^6 = \pi$. Therefore, the total frustration of the entire network will be like $F = \frac{f^{1,6} + f^{1,3} + f^{1,4} + f^{1,5} + f^{2,5} + f^{2,6} + f^{3,5}}{12} =$
 $0+2+0+2+0+2+2 \sim 0.67$. The numerically calculated (by con- $\frac{0+2+0+2+0+2+2}{12} \simeq 0.67$. The numerically calculated (by considering LS dynamics over the top of the network) F values mentioned in Figs. $7(a)$ – $7(h)$ are all closely matched with our calculation based on the 0- π rule.

However, as we have mentioned earlier, these types of dynamical graphs are multistable by nature, which may give different *F* index of graph *G* [\[36,37\]](#page-9-0). To avoid such spurious effect, we have calculated the *F* index by adiabatically increasing the negative strength unless the total frustration value saturates in a specific value. Note that most of these graphs contain the inactive links (as corresponding $f_{\text{local}}^{ij} = 0$), but the numerical results fit with our $0-\pi$ proposition for appropriate high negative coupling strength. We have also

FIG. 7. Numerically calculated *F* for 8 different networks with size $N = 6$. Each column represents the same network architecture containing different spanning trees. Branches of the tree are represented using red arcs and the attractive links are shown using black arcs. Using bipartiteness of the tree, 0 and π phases are assigned to each node of the network. Figures are drawn using the software Gephi [\[51\]](#page-9-0). $(K_A = 0.2 \text{ and } K_R = -4.0).$

checked this phenomenon in a network of 100 oscillators (shown in Fig. 8).

Diverse spanning trees (we have traced nine unique trees) have been chosen for that static network. The yellow lines are the theoretically predicted *F* and the blue lines obtained numerically. In higher negative strength $(K_R \simeq -4)$, the theoretical value of F closely match with the numerically calculated *F*.

FIG. 8. Theoretical prediction of *F* based on $0-\pi$ proposition. Prediction of *F* for a network of $N = 100$ nodes with average degree $\langle K \rangle = 4$. Here 9 different spanning trees are considered. Yellow line is the analytically predicted F and blue curve is the numerically obtained *F*.

VIII. CONCLUSIONS

Our work undermines that a group of amplitude oscillators placed over a bipartite network can lead us to antiphase states $(F = 0)$ if the negative links are passed through the branches of a spanning tree. Noticeably, we establish that such partial use of repulsive interactions on undirected complex networks helps to achieve the highest phase difference of π between two adjacent amplitude oscillators depending on network topology. This negative control in a bipartite graph is simple, elegant and cost effective, which can outperform the other random choices of negative links. Next, we investigate the role of spanning trees in a bipartite graph of limit cycle in a broader level: we construct a $0-\pi$ rule to understand the zero frustration. We also uncover the construction of a weakly dense nonbipartite graph for the desired *F* with the help of $0-\pi$ rule. Finally, we have shown that the negative spanning tree of any nonbipartite graph can successfully determine the nonzero *F* value. Our approach can be easily implemented to other limit cycle and Kuramoto dynamics. Also, we can implement the attractive-repulsive technique in phase-frustrated Kuramoto oscillator [\[29\]](#page-9-0) in which the mixed coupling can be constructed through the heterogeneous phase-frustrated values contained within the coupling function. We would like to explore the impact of phase lag to generate antiphase states in the near future. Our investigation also points out to the fact that zero frustration $(F = 0)$, i.e., antiphase synchronization emerges only in the bipartite network, whereas the nonbipartite network reveals positive *F* value irrespective of the setting of negative links within the considered graph. Thus, the dynamical measure *F* serves as a unique fingerprint to distinguish between bipartiteness and nonbipartite structure of a network. In our designed bipartite network of attractive-repulsively coupled amplitude oscillators, oscillators tend to organize their phase values as colors in a solution of two-colorable graph, which is validated using several bipartite networks of various sizes and different average degrees throughout the paper. The study may unfold the coherent and de-synchronization phenomena broadly in an environment of attractive-repulsive interaction. Our perceived study may be helpful to understand underlying frustrated dynamical behavior of neuronal networks [\[42\]](#page-9-0).

APPENDIX: ALGORITHM FOR DESIGNING SUITABLE NETWORK FOR DESIRED FRUSTRATION BASED ON 0-*π* **RULE**

Suppose, the value of *F* at the steady state is given for a network and the configuration of the underlying repulsive tree is also supplied to us, though the exact architecture of the original network of *N* nodes is unknown. So, with the help of that two specified information, which are namely (i) the spanning tree of that network and (ii) the value of *F*, we would like to design network. Then one can address the question in the following way, how to construct a network of *N* nodes having the congruent underlying tree, which can give us the desired *F*? To proceed further, we initiate an algorithm in such a fashion that it will help us to create a new network of *N* nodes containing the same underlying spanning tree, which will adapt itself by adding appropriate links until the desired frustration *F* is reached.

The steps of the algorithm are depicted below precisely:

(1) *F*desired and a spanning tree of a network with *N* nodes are given as inputs.

(2) The vertex set of the spanning tree is decomposed into two disjoint and independent sets *U* and *V* .

(3) We assign π as the phase of each node of *U* and phase 0 for the vertices of *V* (or vice versa).

(4) Two nodes *i* and *j* are chosen arbitrarily either from the set U or from V , so that there is no link in between those nodes at prior.

(5) A link is added between these two chosen nodes *i* and *j*, and *F* is calculated for the constructed network using our 0- π proposition.

(6) If $F < F_{\text{desired}}$, then go to step (4) and repeat the process. Otherwise, the process is terminated.

Our constructed network is capable of giving rise to the given *F*_{desired}, which we verify by assigning Landau-Stuart oscillators as the local unit dynamics on the newly constructed network and integrate it with Runge-Kutta-Fehlberg method with an error estimator of order $O(h^5)$, where $h = 0.01$ is the step length. We avoid the multistability effect by adiabatically changing the negative strength from 0 to -4 until the *F* is reached to asymptotically saturated value. We have collected the numerical frustration index *F* from the saturated domain to match with our theoretical prediction.

To attain the given *F*desired with the given spanning tree using our algorithm, we need total number of attractive links *m*, which satisfies the following relation,

$$
F_{\text{desired}} = \frac{2m}{L},
$$

i.e.,

$$
F_{\text{desired}} = \frac{2m}{m + (N - 1)},
$$

which gives

$$
m = \left\lceil \frac{(N-1)F_{\text{desired}}}{2 - F_{\text{desired}}}\right\rceil, \quad 0.0 \leq F_{\text{desired}} < 2.0. \quad \text{(A1)}
