

Higher-order percolation processes on multiplex hypergraphsHanlin Sun ¹ and Ginestra Bianconi ^{1,2}¹*School of Mathematical Sciences, Queen Mary University of London, London E1 4NS, United Kingdom*²*The Alan Turing Institute, The British Library, 96 Euston Road, London NW1 2DB, United Kingdom*

(Received 12 April 2021; accepted 19 August 2021; published 15 September 2021)

Higher-order interactions are increasingly recognized as a fundamental aspect of complex systems ranging from the brain to social contact networks. Hypergraphs as well as simplicial complexes capture the higher-order interactions of complex systems and allow us to investigate the relation between their higher-order structure and their function. Here we establish a general framework for assessing hypergraph robustness and we characterize the critical properties of simple and higher-order percolation processes. This general framework builds on the formulation of the random multiplex hypergraph ensemble where each layer is characterized by hyperedges of given cardinality. We observe that in presence of the structural cutoff the ensemble of multiplex hypergraphs can be mapped to an ensemble of multiplex bipartite networks. We reveal the relation between higher-order percolation processes in random multiplex hypergraphs, interdependent percolation of multiplex networks, and K -core percolation. The structural correlations of the random multiplex hypergraphs are shown to have a significant effect on their percolation properties. The wide range of critical behaviors observed for higher-order percolation processes on multiplex hypergraphs elucidates the mechanisms responsible for the emergence of discontinuous transition and uncovers interesting critical properties which can be applied to the study of epidemic spreading and contagion processes on higher-order networks.

DOI: [10.1103/PhysRevE.104.034306](https://doi.org/10.1103/PhysRevE.104.034306)**I. INTRODUCTION**

Higher-order networks [1–5] and multilayer networks [6–8] are generalized network structures that capture the topology of complex systems beyond the single network framework.

Higher-order networks include both hypergraphs and simplicial complexes and encode the set of higher-order interactions present in systems as different as social [9–13], ecological [14], and brain networks [15]. Multilayer networks represent complex systems in which interactions of different nature and connotation can exist forming networks of networks. As such multilayer networks and in particular multiplex networks are becoming the new paradigm to describe social, financial as well as biological networks [6–8].

Higher-order networks and multilayer networks display a very rich interplay between their structure and their dynamics [6]. Notably multilayer networks are characterized by very relevant correlations [16,17] that have the ability to modify the critical properties of the dynamics defined on these structures. On their turn, higher-order networks reveal unexpected phenomena in the context of synchronization transitions [18–22], diffusion [23–26], and spreading processes [10–13,27–29].

In this work we investigate the interplay between structure and the dynamics of higher-order networks providing a comprehensive multilayer framework to study higher-order percolation processes on hypergraphs.

Percolation [30–33] is a fundamental dynamical process defined on networks that predicts the fraction of nodes in the giant component of a network. Having a nonzero giant

component is the minimal requisite for observing collective phenomena on networks, emerging from epidemic spreading, diffusion, and opinion dynamics. Therefore, studying percolation of a given network has important consequences for investigating a wide range of dynamical properties defined on networks.

Percolation theory has been extensively studied in single networks since the early days of network science [30–33]. In particular, node and link percolation have been investigated in random networks with arbitrary degree distribution. In node percolation nodes are initially damaged with probability $1 - p$, in link percolation links are initially damaged with probability $1 - p$. In both percolation models the fraction of nodes in the giant component is studied as a function of p characterizing how the network is dismantled/disconnected by increasing the entity of the initial damage. Interestingly, it has been found that the critical properties of percolation are strongly affected by the network topology of the underlying network. In particular, a classic result of percolation theory is that scale-free networks are robust to random damage and in the infinite network limit can sustain a nonzero fraction of nodes in the giant component for any nonzero value of p [34,35]. While percolation on single networks is a continuous second order transition, K -core percolation [36,37], studying the emergence of the K -core with $K \geq 2$ in complex networks can display a discontinuous hybrid transition if the degree distribution of the network has finite second moment.

With the recent surge of interest on generalized network structures percolation theory has further expanded thanks to the formulation of the interdependent percolation in

multiplex networks that displays a discontinuous hybrid transition in correspondence of large avalanches of failure events [6,38–40]. In interdependent percolation the order parameter is the fraction of nodes in the mutually connected giant component that is the giant component formed by nodes connected by at least one path in each layer of the multiplex network. Interdependent percolation on multiplex networks is highly affected by the correlations [16,17,41] of the underlying multiplex network structure. Indeed, both interlayer degree correlations [16] and link overlap [42–44] have been shown to have a very significant effect on the critical properties of interdependent percolation. This field has been growing at a very fast pace and many results related to the robustness and resilience of multiplex networks have been obtained including the formulation of interdependent percolation in network of networks [45], weak percolation [46,47], optimal percolation [48,49], combinatorial optimization problems [50], K -core multiplex percolation [51], and percolation with redundant interdependencies [52].

This very important subject in network theory has contributed to a much deeper theoretical understanding of the mechanisms leading to discontinuous percolation transitions in complex networks (see recent review articles [53,54]).

Recently the rich interplay between network geometry and topology and the critical properties of the percolation transition on higher-order networks has also gained increasing attention. Hyperbolic simplicial complexes which can be treated within the real-space renormalization group [55–59], have been shown to reveal a rich phase diagram including discontinuous transitions for standard link percolation. Moreover, homological percolation [60,61] has been shown to characterize the emergence of a nontrivial homology for higher-order network topologies.

The critical properties of higher-order percolation process on random hypergraphs which do not display an hyperbolic network geometry have not yet been explored exhaustively despite some interesting results related to core percolation in hypergraphs have been recently published in Ref. [62]. Indeed, so far the investigation of percolation on random hypergraphs has been restricted to very simple cases of hypergraphs whose hyperedges have fixed cardinality [63,64].

In this paper we relate higher-order percolation on hypergraphs to generalized percolation processes in multiplex networks. Random hypergraphs can have a nontrivial underlying multiplex topology leading to the definition of random multiplex hypergraphs in which each layer captures the set of hyperedges of a given cardinality [12,13]. In this work we will demonstrate that multiplex hypergraphs are ideal statistical mechanics tools to study a large variety of higher-order percolation processes of hypergraphs with a wide range of applications. Moreover, multiplex hypergraphs can admit also a physical interpretation when different layers characterize interactions of different nature. For instance a multiplex hypergraph containing pairwise interactions and higher-order interactions can be used to study the interplay between blood-vessel pairwise connectivity between brain regions [65] and their higher-order functional brain interactions [15]. Similarly in social networks pairwise interactions can be associated to pairwise communication such as mobile-phone communications [66] or friendships in online

social networks while higher-order interactions can describe higher-order face-to-face communication or group discussions around information posted online [67,68]. In this work we define ensembles of random multiplex hypergraphs in which each node i is assigned nonscalar generalized degree $\mathbf{k}_i = (k_i^{[1]}, k_i^{[2]}, \dots, k_i^{[m]}, \dots, k_i^{[M]})^\top$ where $k_i^{[m]}$ indicates the number of hyperedges of cardinality m incident to node i . As such multiplex hypergraphs are characterized by important interlayer generalized hyperdegree correlations. Interestingly, we note that a multiplex hypergraph ensemble is, in general, distinct from a multiplex bipartite network where each factor node corresponds to an hyperedge. However, it is possible to map one ensemble in the other in presence of a structural cutoff. Here we show that standard percolation is affected by the nontrivial topology of multiplex hypergraphs and by their interlayer correlations that can be tuned to increase or decrease the percolation threshold of the hypergraph. Most importantly our work reveals how the multiplex nature of the multiplex hypergraph ensembles can be exploited to propose higher-order percolation problems displaying a rich interplay between higher-order topology and dynamics and a rich set of phenomena, including discontinuous hybrid transitions and multiple percolation transitions.

The paper is structured as follows: in Sec II we present the random multiplex hypergraph model and we compare the model with the already widely used model of random hypergraphs; in Secs. III and IV we investigate the properties of standard node and link percolation on the random hypergraphs and on the random multiplex hypergraphs, respectively; in Sec. V we provide a general framework to study higher-order percolation processes on random multiplex hypergraphs; finally, in Sec. VI we provide the concluding remarks.

II. HYPERGRAPHS MODELS

A. Random hypergraphs

In this paragraph we introduce random hypergraphs used widely in the literature. This model will be subsequently compared with the model of random multiplex hypergraph which allows us to capture more rich hypergraphs topologies. Hypergraphs $\mathcal{H} = (V, H)$ are formed by a set V of N nodes and a set H of hyperedges of different cardinality $m \leq M$. The number of hyperedges incident to a node is also called its *hyperdegree*. Therefore, if all hyperedges have cardinality $m = 2$, i.e., all hyperedges are essentially links describing pairwise interactions, then the hypergraph reduces to a network, and the definition of hyperdegree reduces to the definition of degree. In general, in hypergraphs containing hyperedges of different cardinality, the hyperdegree counts the number of hyperedges incident to a node regardless of their cardinality.

The simplest model of hypergraph here called the *random hypergraph model* is a maximum entropy hypergraph model with given hyperdegree distribution $P(k)$ and distribution $\hat{P}(m)$ of hyperedge cardinalities. Therefore, as far as a node has a given hyperdegree k drawn from the hyperdegree distribution $P(k)$, the model is agnostic on the cardinality of its incident hyperedges.

The maximum entropy ensemble of random hypergraphs is related to factor graphs. Factor graphs are bipartite networks

$G_B(V, U, E)$ formed by a set of nodes V and a set of factor nodes U which do not overlap and a set E of pairwise interactions with each interaction linking a node to a factor node. Every hypergraph can be mapped to a factor graph by the following mapping. The set V of nodes of the hypergraph maps to the set V nodes of the factor graph. Each hyperedge of the hypergraph is in correspondence with a factor node in U . Note however that the opposite is not always true, i.e., a factor graphs do not always map to (unweighted) hypergraphs as it is not excluded a priori that two factor nodes connect the same set of nodes. Despite factor graphs are typically not reducible to unweighted random hypergraphs, if the factor graph is sufficiently sparse, i.e., they display a structural cutoff, the probability that more than one factor node is connected to the same set of nodes is negligible. In this regime, which corresponds to the sparse factor graph regime, we can map an unweighted random hypergraph to a factor graph. In this limit we have that the hyperdegree distribution $P(k)$ and distribution $\hat{P}(m)$ of hyperedge cardinalities correspond to the degree distribution of the nodes and of the factor nodes of the factor graph, respectively.

In the uncorrelated hypergraph ensemble, as long as the hyperdegree distribution and the distribution of hyperedge cardinality have a structural cutoff, the probability that node i is connected to hyperedge α is given by

$$\tilde{p}_{i\alpha} = \frac{k_i m_\alpha}{\langle k \rangle N}, \tag{1}$$

where k_i indicates the hyperdegree of node i and m_α indicates the cardinality of the hyperedge/factor node α . The corresponding hypergraph includes a hyperedge $\alpha = [i_1, i_2, \dots, i_m]$ with probability [4]

$$p_{[i_1, i_2, \dots, i_m]} = (m - 1)! \frac{\prod_{r=1}^m k_{i_r}}{(\langle k \rangle N)^{m-1}}. \tag{2}$$

B. Random multiplex hypergraphs

The random hypergraphs described in the previous paragraph are maximum entropy ensembles in which we fix the hyperdegree of each node. Here we consider hypergraphs in which we assign to each node a set of generalized hyperdegrees each one fixing the incident number of hyperedges of a given cardinality. This allows to control the number of hyperedges of a given cardinality incident to each node providing a more refined hypergraph model than the random hypergraph.

As we will see this model can be mapped to a multiplex network model [6,41], hence we indicate this model as *random multiplex hypergraph*.

In this case, as in the previous case, we consider an ensemble of hypergraphs $\mathcal{H} = (V, H)$ formed by a set V of N nodes and a set H of hyperedges of different cardinality $m \leq M$. The hypergraph \mathcal{H} in the multiplex hypergraph ensemble is determined by a set tensors of dimension $2 \leq m \leq M$ where the m -th tensor $\mathbf{a}^{[m]}$ determines all the hyperedges of dimension m , i.e., it has elements $a_{i_1 i_2 \dots i_m}^{[m]} = 1$ only if $\alpha = [i_1, i_2, \dots, i_m] \in H$; otherwise, $a_{i_1 i_2 \dots i_m}^{[m]} = 0$. Each node i is assigned a set of generalized hyperdegrees,

$$\mathbf{k}_i = (k_i^{[2]}, k_i^{[3]}, \dots, k_i^{[M]}), \tag{3}$$

where $k_i^{[m]}$ indicates the number of hyperedges of degree m incident node i , i.e.,

$$k_i^{[m]} = \sum_{j_1, j_2, \dots, j_{m-1}} a_{i, j_1, j_2, \dots, j_{m-1}}^{[m]}. \tag{4}$$

For these hypergraphs we can define the generalized hyperdegree distribution $P(\mathbf{k})$ as the probability that a random node of the hypergraph has generalized hyperdegrees $\mathbf{k}_i = \mathbf{k}$ with $\mathbf{k} = (k_1, k_2, \dots, k_m, \dots, k_M)^\top$.

The *random multiplex hypergraph* is the maximum entropy hypergraph model with given generalized hyperdegree distribution $P(\mathbf{k})$ and given distribution $\hat{P}(m)$ of cardinality of the hyperedges. This model can be mapped to a multiplex network model in which each layer capture interactions of a given cardinality [12,13]. The random multiplex hypergraph is a very useful statistical mechanics tool to model unbiased random hypergraphs with hyperdegree correlations, but it can also have a very relevant physical interpretation when hyperedges of different cardinality are associated to interactions of different nature and connotation. In particular, this statistical mechanics construction can be useful in brain networks to distinguish between brain regions connected pairwise by blood-vessels [65] and higher-order functional brain interactions [15] or can be useful to model social networks in which we want to distinguish between pairwise interactions (as phone call interactions) [66] and face-to-face interactions [67,68] or online interactions between more than two people.

In the hypergraph setting there are no constraints relating hyperedges of different cardinality. Therefore, the hyperedges of different cardinality can be drawn independently. This is different from what happens in the simplicial complex setting which are closed under the inclusion of subsets of any given simplex. Despite this difference, simplicial complex models can be very efficiently used to model hypergraphs. Indeed, the maximum entropy hypergraph with given generalized hyperdegree sequences can be constructed starting from the well establish configuration model of pure simplicial complexes [4,69] by mapping the hypergraph to a multiplex network [12,13] in which every layer indicates the interactions described by hyperedges of a given size m .

The algorithm to construct a random multiplex hypergraph (see Fig. 1) is as follows:

(1) Consider a multiplex networks with $M - 1$ layers m with $2 \leq m < M$ and N nodes corresponding to the N nodes of the hypergraph.

(2) For each layer m consider configuration model of pure $(m - 1)$ -dimensional simplicial complexes [4] (codes available at the repository [69]) with generalized degree sequence

$$\{k^{[m]}\}_{i=1,2,\dots,N} = \{k_1^{[m]}, k_2^{[m]}, \dots, k_N^{[m]}\}. \tag{5}$$

From this simplicial complex extract the hypergraph formed only by the simplicial complex facets. This hypergraph is defined by a tensor $\mathbf{a}^{[m]}$ describing all the m -body interactions of the multiplex hypergraph. For simplicity we assume that the hyperdegrees $\{k_i^{[m]}\}$ display a structural cutoff $\tilde{K}^{[m]}$ given by

$$\tilde{K}^{[m]} = \left[\frac{(\langle k^{[m]} \rangle N)^{m-1}}{(m - 1)!} \right]^{1/m}. \tag{6}$$

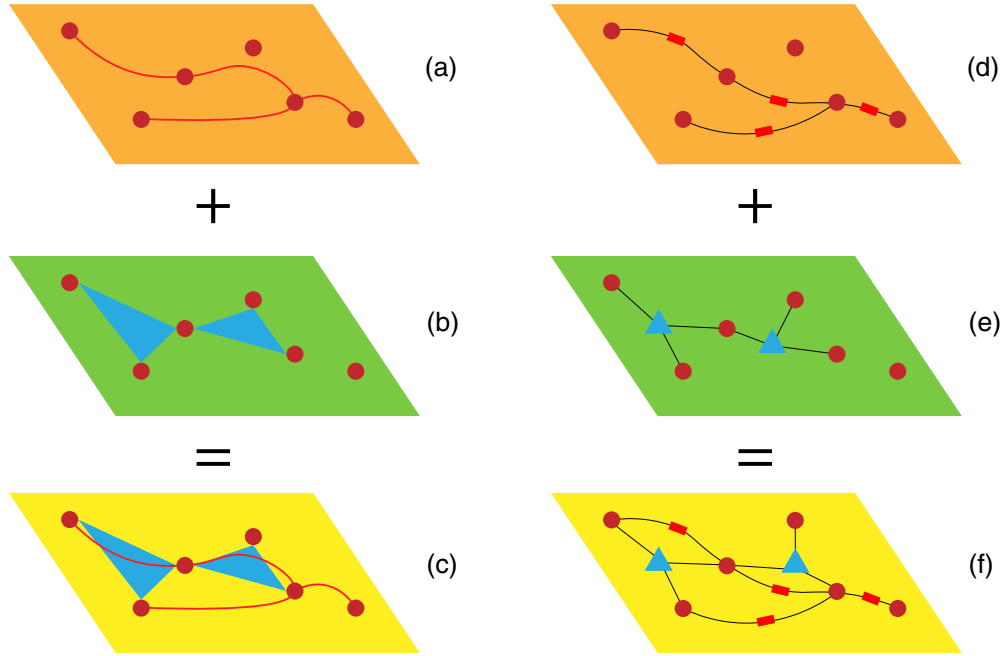

FIG. 1. A schematic representation of the multiplex network construction of the hypergraph with given generalized hyperdegree sequences for hyperedges of cardinality $m_1 = 2$ (layer 1) and $m_2 = 3$ (layer 2). First a configuration model is used to generate a simple network capturing the two-body interactions of the hypergraph (a). Second, the configuration model of simplicial complexes [4] is used to generate a pure simplicial complex formed exclusively by triangles. Only the information about the three-body interactions is retained (b). Finally, the information of the different layers is aggregated to generate the desired hypergraph including hyperedges of size $m = 2$ and $m = 3$ (c). This construction can be generalized to an arbitrary number of layers. The factor graph representation of the multiplex hypergraph is shown in panels (d), (e), and (f).

In this hypothesis the probability $p_{[i_1, i_2, \dots, i_m]}^{[m]}$ of the hyperedge $[i_1, i_2, \dots, i_m]$ is given by [4]

$$p_{[i_1, i_2, \dots, i_m]}^{[m]} = (m-1)! \frac{\prod_{r=1}^m k_{i_r}^{[m]}}{(\langle k^{[m]} \rangle N)^{m-1}}. \quad (7)$$

Note that some layers might be empty if

$$\sum_{i=1}^N k_i^{[m]} = 0. \quad (8)$$

In this case, the number of layers of the random multiplex hypergraph is given by the number M' of layers with at least one hyperedge.

(3) Consider the hypergraph obtained by aggregating all the layers, i.e., considering all the interactions of different sizes $2 \leq m < M$. Note that this aggregated hypergraph, differently from the aggregated multiplex network with pairwise interactions, retains its multilayer nature as the hyperedges of different cardinality can be easily distinguished also in the aggregated version of the hypergraph. Therefore, we will not make a distinction between this aggregated hypergraphs and their multiplex representation.

Despite, in general, a random multiplex hypergraph is distinct from a multiplex factor graph as factor graphs can have more than two factor nodes connected to the same set of nodes, in the sparse regime of uncorrelated random multiplex hypergraphs displaying a structural cutoff we can, in the infinite network limit, consider the two ensembles as equivalent. In this factor graph interpretation, the probability that node i is connected to factor node α in a given layer describing m -body

interactions, i.e., with $m_\alpha = m$ is given by

$$\tilde{p}_{i\alpha} = \frac{k_i^{[m]} m}{\langle k^{[m]} \rangle N}. \quad (9)$$

The mapping between the hypergraph model with given generalized hyperdegree sequences and multiplex networks, allows us to address the role of correlations have in this hypergraph model. Indeed, by considering a parallelism to multiplex networks we can investigate different types of possible correlations in hypergraph models. First of all the hyperdegrees \mathbf{k} of a given nodes can be correlated. In a hypergraph including $m = 2$ and $m = 3$ hyperedges positive generalized hyperdegree correlations indicate for instance that nodes with many two-body interactions have also many three-body interactions and nodes with few two-body interactions have also few three-body interactions. On the contrary negative correlations of generalized hyperdegrees will imply that nodes with many two-body interactions will participate in few three-body interactions and vice-versa. Second, we might be interested in the overlap between hyperedges of different cardinality. This implies that in a hypergraph including $m = 2$ and $m = 3$ hyperedges, we might be interested to assess how many two-body interactions connect nodes already connected in three-body interactions.

In this work we will focus in particular in the effect of the correlations between generalized hyperdegrees on the robustness properties of hypergraphs. Indeed, we notice that in the considered hypergraph ensemble hyperedges do not have a significant overlap. To show that we define the total

overlap $O^{[m,n]}$ between m -hyperedges and n -hyperedges with $n > m$ as

$$O^{[m,n]} = \sum_{\alpha \in Q_{[m]}} a_{\alpha}^{[m]} A_{\alpha}^{[n]}, \quad (10)$$

where $Q_{[m]}$ indicates the set m -tuples of nodes of the hypergraph and $A_{\alpha}^{[n]} = 1$ if and only if α is a subset of nodes of an existing n -hyperedges; otherwise, $A_{\alpha}^{[n]} = 0$. The average overlap $\langle O^{[m,n]} \rangle$ over the hypergraph ensemble with marginals given by Eq. (7) reads

$$\langle O^{[m,n]} \rangle = \sum_{\alpha \in Q_{[m]}} p_{\alpha}^{[m]} p_{\alpha}^{[n,m]}, \quad (11)$$

where $p_{\alpha}^{[m]}$ is given by Eq. (7) and where $p_{\alpha}^{[n,m]} = \langle A_{\alpha}^{[n]} \rangle$ is given by

$$p_{[i_1, i_2, \dots, i_m]}^{[n,m]} = \frac{(n-1)!}{(n-m)!} \frac{\prod_{r=1}^m k_{i_r}^{[n]}}{(\langle k^{[n]} \rangle N)^{m-1}}. \quad (12)$$

This implies that the average overlap $\langle O^{[m,n]} \rangle$ is negligible for $N \gg 1$ as it scales as

$$\langle O^{[m,n]} \rangle = \frac{(n-1)!(m-1)!}{(n-m)!m!} \frac{\langle k^{[n]} k^{[m]} \rangle^m}{\langle k^{[n]} \rangle^{m-1} \langle k^{[m]} \rangle^{m-1} N^{m-2}}, \quad (13)$$

(see analogous treatment for multilayer networks in Ref. [41]). Therefore, the overlap of hyperedges is negligible in the sparse regime where the marginals are expressed by Eq. (7).

III. PERCOLATION ON RANDOM HYPERGRAPHS

Percolation on random uncorrelated hypergraphs can be treated directly by extending the ideas and concepts of percolation on factor graphs. Therefore, since the factor graph corresponding to a random hypergraph is locally treelike we can write self-consistent equations for the probability \hat{S} that starting from a node and following a link we reach a factor node (hyperedge) in the giant component and for the probability S that starting from a factor node (hyperedge) and following a link of the factor graph we reach a node in the giant component. Assuming that each node is not initially damaged with probability $p^{[N]}$ and each hyperedge is not initially damaged with probability $p^{[H]}$ the self consistent equations for S and \hat{S} read

$$\begin{aligned} \hat{S} &= p^{[H]} \sum_m \frac{m}{\langle m \rangle} \hat{P}(m) [1 - (1 - S)^{m-1}], \\ S &= p^{[N]} \sum_k \frac{k}{\langle k \rangle} P(k) [1 - (1 - \hat{S})^{k-1}]. \end{aligned} \quad (14)$$

A diagrammatic representation of these two equations is shown in Fig. 2.

The percolation problem is fully characterized by its order parameters given by the probability R of finding a node in the giant component and the probability \hat{R} of finding a hyperedge in the giant component. In a random hypergraph, these order

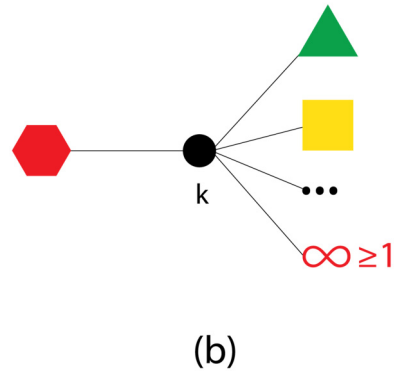

FIG. 2. An schematic illustration of Eqs. (14) for \hat{S} and S are shown in panels (a) and (b), respectively. Black circles represent nodes; triangles, squares, and hexagons represent factor nodes (hyperedges) with different cardinality.

parameters can be expressed in terms of \hat{S} and S as

$$\begin{aligned} R &= p^{[N]} \left(1 - \sum_k P(k) (1 - \hat{S})^k \right), \\ \hat{R} &= p^{[H]} \left(1 - \sum_m \hat{P}(m) (1 - S)^m \right). \end{aligned} \quad (15)$$

These equations together with the self-consistent Eqs. (14) can be used to investigate the critical properties of percolation inferring the robustness of the random hypergraph. In particular, we can impose $p^{[H]} = 1$ (or $p^{[N]} = 1$) and to characterize node percolation (or hyperedge percolation) where only hyperedges are randomly removed (or node percolation where only nodes are randomly removed). If the hypergraph only contains hyperedges of cardinality $m = 2$ (i.e., it reduces to a network), then these two percolation problems reduce to link and node percolation, respectively. In Fig. 3 we show R versus $p^{[H]} = p$ for hyperedge percolation ($p^{[N]} = 1$) when both the hyperdegree distribution and the distribution of cardinalities of hyperedges are Poisson distributed. The critical point of the general percolation problem defined in Eq. (15) is characterized by the critical thresholds $p_c^{[H]}$ and $p_c^{[N]}$. By imposing that the largest eigenvalue of the Jacobian matrix of Eqs. (14) is equal to one at $S = \hat{S} = 0$, we find that $p_c^{[H]}$ and $p_c^{[N]}$ must satisfy

$$p_c^{[N]} p_c^{[H]} \frac{\langle k(k-1) \rangle}{\langle k \rangle} \frac{\langle m(m-1) \rangle}{\langle m \rangle} = 1. \quad (16)$$

FIG. 3. The fraction of nodes in the giant component R is shown versus $p^{[H]} = p$ for random hypergraphs. The hyperdegree distribution $P(k)$ and distribution of cardinality of hyperedges $\hat{P}(m)$ are Poisson distribution, with different expectation $\langle m \rangle$ and $\langle k \rangle$.

Therefore, for hyperedge percolation in which $p^{[N]} = 1$ we obtain that the critical threshold $p_c^{[H]}$ satisfies

$$p_c^{[H]} \frac{\langle k(k-1) \rangle}{\langle k \rangle} \frac{\langle m(m-1) \rangle}{\langle m \rangle} = 1, \quad (17)$$

for node percolation in which $p^{[H]} = 1$ we obtain that the critical threshold $p_c^{[N]}$ satisfies

$$p_c^{[N]} \frac{\langle k(k-1) \rangle}{\langle k \rangle} \frac{\langle m(m-1) \rangle}{\langle m \rangle} = 1. \quad (18)$$

We note that Eqs. (17) and (18), fixed to the hyperedge and the node percolation thresholds, are invariant if we permute the distributions $P(k)$ and $\hat{P}(m)$. This effect can be seen also in Fig. 3 where it is evident that the hyperedge percolation thresholds of two random hypergraphs with Poisson $P(k)$ and Poisson $\hat{P}(m)$ is the same if for the first hypergraph $\langle k \rangle = 2$ and $\langle m \rangle = 4$ and for the second hypergraph $\langle k \rangle = 4$ and $\langle m \rangle = 2$.

Finally, we note that if the hypergraph is formed only by m -hyperedges, the distribution $\hat{P}(m')$ reduces to a δ function:

$$\hat{P}(m') = \delta_{m',m}, \quad (19)$$

and Eq. (16) reduces to

$$p_c^{[N]} p_c^{[H]} (m-1) \frac{\langle k(k-1) \rangle}{\langle k \rangle} = 1. \quad (20)$$

This last equation reduces to results obtained in Refs. [63,64].

IV. PERCOLATION ON RANDOM MULTIPLEX HYPERGRAPHS

A. General framework

We consider percolation on random multiplex hypergraphs, i.e., hypergraphs with given generalized hyperdegree sequences when nodes are not initially damaged with probability $p^{[N]}$ and hyperedges are not initially damaged with

probability $p^{[H]}$. To characterize percolation on these hypergraphs we consider their corresponding factor graphs. In particular, we indicate with \hat{S}_m the probability that by following a link of a node in layer m we reach a m -factor node (m hyperedge) that belongs to the giant component. Moreover, with S_m we indicate the probability that following a link of a m -factor node (m hyperedge) in layer m we reach a node in the giant component. Since the corresponding multiplex factor graph of the random multiplex hypergraph is locally treelike the probabilities \hat{S}_m and S_m can be found to satisfy the self-consistent equations

$$\begin{aligned} \hat{S}_m &= p^{[H]} [1 - (1 - S_m)^{m-1}], \\ S_m &= p^{[N]} \sum_{\mathbf{k}} \frac{k_m}{\langle k_m \rangle} P(\mathbf{k}) \left[1 - \prod_{m'} (1 - \hat{S}_{m'})^{k_{m'} - \delta_{m,m'}} \right]. \end{aligned} \quad (21)$$

These self-consistent equations have a diagrammatic interpretation as shown in Fig. 4. In particular, \hat{S}_m indicates the probability that a m -factor node (m hyperedge) reached by following a link in layer m , is not initially damaged and it is connected at least to a node in the giant component. Instead, S_m indicates the probability that a node reached by following a link in layer m is not initially damaged and it is connected at least to one factor node (hyperedge)—of any possible cardinality—in the giant component.

The order parameters for percolation on a random multiplex hypergraph are given by the expected fraction of nodes R and the expected fraction of hyperedges \hat{R} in the giant component, given by

$$\begin{aligned} R &= p^{[N]} \left[1 - \sum_{\mathbf{k}} P(\mathbf{k}) \prod_m (1 - \hat{S}_m)^{k_m} \right], \\ \hat{R} &= p^{[H]} \left[1 - \sum_m \hat{P}(m) (1 - S_m)^m \right]. \end{aligned} \quad (22)$$

Equations (22) together with the Eqs. (21) fully determine the percolation process on random multiplex hypergraphs and can be used to study the robustness of these structures as a function of the hyperdegree distribution $P(\mathbf{k})$ and the distribution of cardinality of the hyperedges $\hat{P}(m)$. In particular, they can be used to investigate the effect that correlations between the hyperdegrees on different layers have on the robustness properties of the multiplex hypergraph.

One fundamental measure for characterizing the robustness of a multiplex hypergraph with respect to another hypergraph is without any doubt the characterization of the percolation threshold. Indeed, a smaller node (or hyperedge) percolation threshold implies that an hypergraph can display a giant component also when a larger fraction of nodes (or hyperedges) is removed.

Close to the percolation transition, for $0 < S_m \ll 1$ and $0 < \hat{S}_m \ll 1$, Eqs. (21) can be linearized to

$$\begin{aligned} \hat{S}_m &= p^{[H]} (m-1) S_m, \\ S_m &= \sum_n G_{mn} S_n, \end{aligned} \quad (23)$$

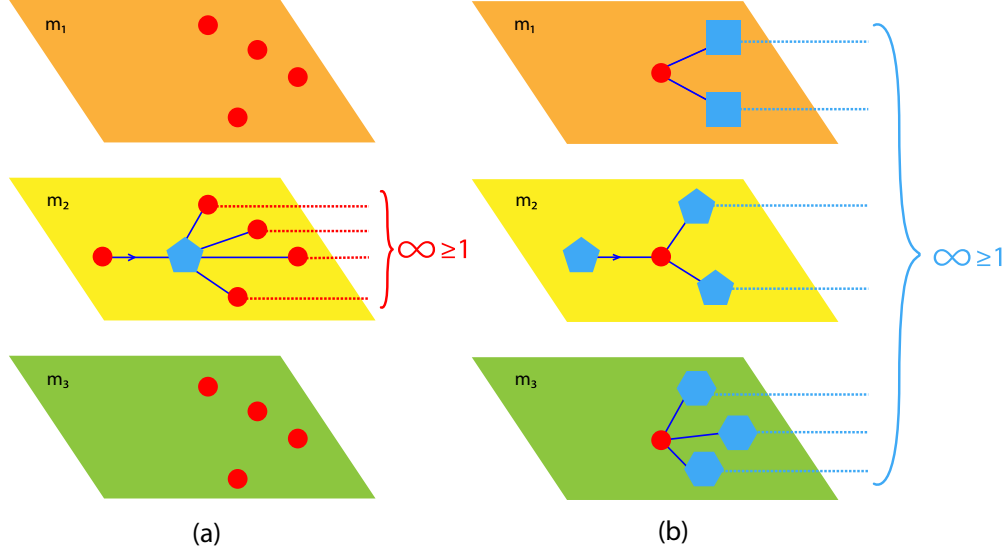

FIG. 4. A schematic illustration of Eqs. (21) for \hat{S}_m and S_m are shown in panels (a) and (b), respectively. Red circles represent nodes; squares, pentagons, and hexagons represent factor nodes (hyperedges) with different cardinality.

where the matrix \mathbf{G} has elements

$$G_{mn} = \begin{cases} p_c^{[H]} p_c^{[N]} (n-1) \langle k_n k_m \rangle / \langle k_m \rangle & \text{for } m \neq n, \\ p_c^{[H]} p_c^{[N]} (m-1) \langle k_m (k_m - 1) \rangle / \langle k_m \rangle & \text{for } m = n. \end{cases} \quad (24)$$

Therefore, node and hyperedges critical thresholds $p_c^{[N]}$ and $p_c^{[H]}$ can be obtained by imposing that the largest eigenvalue Λ of \mathbf{G} is one, i.e.,

$$\Lambda = 1. \quad (25)$$

In the following sections we will predict the percolation threshold in important examples of random multiplex hypergraphs and we will characterize the role that correlations among hyperdegree of different layers have on the robustness properties of random multiplex hypergraphs.

B. Percolation threshold in some specific cases

1. Hypergraph with fixed cardinality of hyperedges

For a single-layer multiplex hypergraph including only hyperedges of cardinality m , i.e., only including m -body interactions, we have

$$\hat{P}(m') = \delta_{m,m'}. \quad (26)$$

In this case, the matrix \mathbf{G} reduces to a scalar G given by

$$G = G_{mm} = p_c^{[N]} p_c^{[H]} (m-1) \frac{\langle k_m (k_m - 1) \rangle}{\langle k_m \rangle}. \quad (27)$$

Therefore, the percolation thresholds are obtained by imposing $G = 1$, giving

$$p_c^{[N]} p_c^{[H]} (m-1) \frac{\langle k_m (k_m - 1) \rangle}{\langle k_m \rangle} = 1. \quad (28)$$

It follows that in this simple case we recover the expression in Eq. (20) as we should.

2. Independent layers with Poisson generalized degree distribution

A more interesting case in which we can appreciate the multiplex structure of the problem is given by the case in which the hyperdegree distribution of each layer of the random multiplex hypergraphs is an independent Poisson distribution with layer-dependent average hyperdegree z_m . In this case, the joint hyperdegree distribution $P(\mathbf{k})$ is given by

$$P(\mathbf{k}) = \prod_m P_m(k_m), \quad (29)$$

with $p_m(k_m)$ given by

$$P_m(k_m) = \frac{e^{-z_m} z_m^{k_m}}{k_m!}. \quad (30)$$

By using the well-known expression for the moments of Poisson distribution, it is easy to check that

$$\frac{\langle k_n k_m \rangle}{\langle k_n \rangle} = z_m, \quad \frac{\langle k_m (k_m - 1) \rangle}{\langle k_m \rangle} = z_m. \quad (31)$$

Thus, we obtain that for this random multiplex hypergraph the matrix \mathbf{G} has elements G_{mn} given by

$$G_{mn} = p_c^{[H]} p_c^{[N]} (m-1) z_m. \quad (32)$$

Since the matrix elements G_{mn} only depend on the index m (i.e., every row m of \mathbf{G} is formed by elements having the same numerical value) the rank of \mathbf{G} is equal to one, i.e., $\text{rank}(\mathbf{G}) = 1$. This implies that the only nonzero eigenvalue Λ of \mathbf{G} equals the trace of this matrix:

$$\Lambda = \text{Tr}(\mathbf{G}) = p_c^{[N]} p_c^{[H]} \sum_m (m-1) z_m. \quad (33)$$

By imposing that $\Lambda = 1$ we find that the critical thresholds $p_c^{[N]}$ and $p_c^{[H]}$ satisfy

$$\frac{1}{p_c^{[N]} p_c^{[H]}} = \sum_m (m-1) z_m. \quad (34)$$

This equation can be used to elucidate the relation between the percolation thresholds of the Poisson multiplex hypergraph and the percolation threshold of single-layer Poisson hypergraphs constructed by considering only the hyperedges of a given size. Indeed, Eq. (34) implies that

$$\frac{1}{p_c^{[N]} p_c^{[H]}} = \sum_m \frac{1}{p_c^{[N,m]} p_c^{[H,m]}}, \quad (35)$$

where $p_c^{[N,m]}$ and $p_c^{[H,m]}$ with

$$p_c^{[N,m]} p_c^{[H,m]} = [(m-1)z_m]^{-1}, \quad (36)$$

indicating the critical node and hyperedge percolation thresholds of hypergraphs obtained by considering only the m -body iterations in layer m . This implies that the product of the percolation threshold $p_c^{[N]} p_c^{[H]}$ for the multiplex hypergraph model is smaller than the corresponding product of percolation threshold $p_c^{[N,m]} p_c^{[H,m]}$ for each single layer of the multiplex hypergraph. Therefore, the multiplex hypergraph is more robust than every of its layers taken in isolation.

3. Independent layers with power-law generalized degree distribution

Another interesting case of random multiplex hypergraph is the one formed by independent layers each one with power-law generalized hyperdegree distribution. In this case, the joint hyperdegree distribution $P(\mathbf{k})$ is given by

$$P(\mathbf{k}) = \prod_m P_m(k_m), \quad (37)$$

with

$$P_m(k_m) = c_m k_m^{-\gamma_m}, \quad (38)$$

with $\gamma_m > 2$ and c_m indicating the normalization constant. For this random multiplex hypergraph the matrix \mathbf{G} has elements

$$G_{mn} = \begin{cases} p^{[H]} p^{[N]} (n-1) \langle k_n \rangle & \text{for } m \neq n, \\ p^{[H]} p^{[N]} (m-1) \langle k_m (k_m - 1) \rangle / \langle k_m \rangle & \text{for } m = n. \end{cases}$$

Given that $\gamma_m > 2$, we have that each layer is sparse, i.e., $\langle k_n \rangle$ is finite at the limit $N \rightarrow \infty$. However, as soon as one layer is associated to a power-law exponent $\gamma_m \in (2, 3]$ the second moment $\langle k_m (k_m - 1) \rangle / \langle k_m \rangle$ diverges in the large network limit $N \rightarrow \infty$. This implies that the trace of \mathbf{G} diverges as well, indicating that the maximum eigenvalue diverges. It follows that as soon as one layer has a scale-free generalized hyperdegree distribution, i.e., as soon as for at least one layer m we have $\gamma_m \in (2, 3]$, then

$$p_c^{[N]} p_c^{[H]} \rightarrow 0, \quad (39)$$

in the limit $N \rightarrow \infty$. This implies that for standard percolation it is enough that one layer is scale-free to significantly improve the robustness of the random multiplex hypergraph.

C. Effect of correlations between generalized hyperdegrees

Random multiplex hypergraphs are characterized, in general, by nontrivial correlations between the hyperdegrees of the same nodes. In particular, given a random multiplex hypergraph we indicate with C_{mn} the correlation between the

hyperdegrees of the same node, connected to hyperedges of cardinality n and m , respectively, i.e.,

$$C_{mn} = \langle k_n k_m \rangle - \langle k_n \rangle \langle k_m \rangle. \quad (40)$$

In a random multiplex hypergraph formed by two layers, this correlations can be modified by permutating the labels of the nodes in a given layer leaving the hyperdegree distribution of the two layers unchanged. In particular, it is possible to choose the permutation of the replica nodes in such a way that the correlations among the corresponding generalized degrees is maximized or minimized generating maximally positive correlated multiplex hypergraphs and maximally negative correlated multiplex hypergraphs. This construction follows very closely the construction to build maximally positive and maximally negative correlated multiplex networks proposed in Ref. [16]. In particular, the maximally positive correlated multiplex hypergraph (MPCMH) can be obtained by ranking the generalized hyperdegrees of both layers in increasing order and identifying the label of the nodes with the same rank in both layer. On the contrary maximally negative correlated multiplex hypergraph (MNCMH) can be obtained by ranking the generalized degrees of one layer in increasing order and the one of the other layer in decreasing order, and by identifying the label of the nodes of the same rank. If the label of the nodes are assigned randomly, then we will obtain an uncorrelated multiplex hypergraph (UMH). To assess the effect of correlations in the robustness of random multiplex hypergraph here we focus on a duplex hypergraph and we investigate the dependence of the percolations thresholds with the correlations coefficient between the generalized hyperdegrees of the two layers. In the considered case of a duplex hypergraph with two layers formed by hyperedges of cardinality m_1 and m_2 , the matrix \mathbf{G} is given by

$$G = p^{[H]} p^{[N]} \begin{pmatrix} \hat{m}_1 \mathcal{K}_1 & \hat{m}_2 \mathcal{K}_1 \\ \hat{m}_1 \mathcal{K}_2 & \hat{m}_2 \mathcal{K}_2 \end{pmatrix}, \quad (41)$$

where $\hat{m}_r = m_r - 1$ for $r \in \{1, 2\}$ and where we have used the notation

$$\frac{\langle k_{m_r} (k_{m_r} - 1) \rangle}{\langle k_{m_r} \rangle} = \kappa_r, \quad \frac{\langle k_{m_1} k_{m_2} \rangle}{\langle k_{m_r} \rangle} = \mathcal{K}_r, \quad (42)$$

for $r \in \{1, 2\}$. The percolation threshold can be found by imposing that the maximum eigenvalue of the matrix \mathbf{G} equals one, obtaining

$$p_c^{[N]} p_c^{[H]} = 2[\kappa_1 \hat{m}_1 + \kappa_2 \hat{m}_2 + \sqrt{\Delta}]^{-1}, \quad (43)$$

with

$$\Delta = (\kappa_1 \hat{m}_1 - \kappa_2 \hat{m}_2)^2 + 4\mathcal{K}_1 \mathcal{K}_2 \hat{m}_1 \hat{m}_2. \quad (44)$$

We observe that for this percolation problem, the node percolation threshold $p_c^{[N]}$ obtained when we impose $p^{[H]} = p_c^{[H]} = 1$ and the hyperedge percolation threshold $p_c^{[H]}$ obtained when we impose $p^{[N]} = p_c^{[N]} = 1$ take the same value. Since the product $\mathcal{K}_1 \mathcal{K}_2$ depends on the correlation coefficient $C_{m_1 m_2}$ through

$$\mathcal{K}_1 \mathcal{K}_2 = \frac{(C_{m_1 m_2} + \langle k_{m_1} \rangle \langle k_{m_2} \rangle)^2}{\langle k_{m_1} \rangle \langle k_{m_2} \rangle}, \quad (45)$$

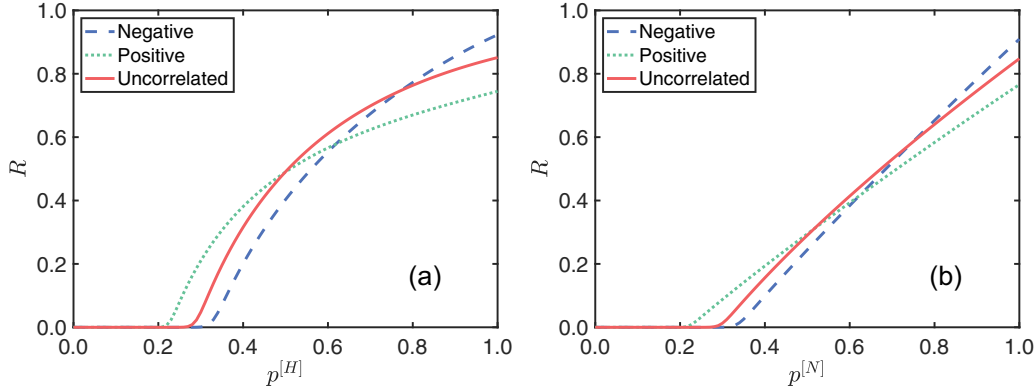

FIG. 5. The fraction R of nodes in the giant component for MPCMH (Positive correlations), for the UMH (Uncorrelated) and for MNCMH (Negative correlations) is shown for hyperedge percolation (a) and for node percolation (b). The considered duplex hypergraph has $N = 10^4$ nodes and hyperedges of cardinality $m_1 = 2$ (layer 1) and $m_2 = 3$ (layer 2). The generalized hyperdegree distributions are Poisson with $z_2 = 0.5$ (for layer 1), $z_3 = 1.5$ (for layer 2).

Eq. (43) reveals that positive correlations increase the robustness of the multiplex hypergraph against random attack while negative correlations decrease the robustness of the multiplex hypergraph. In Fig. 5 we show the effect of degree correlations on the robustness of random multiplex hypergraph by investigating separately node percolation and hyperedge percolation. We observe that the percolation threshold for node and hyperedge percolation are the same and are in perfect agreement with the analytical results indicating that maximally correlated multiplex hypergraphs have a lower percolation threshold than maximally negative correlated multiplex networks. The investigation of the order parameter R versus $p^{[M]}$ in node percolation (when $p^{[H]} = 1$) versus $p^{[H]}$ in hyperedge percolation (when $p^{[N]} = 1$) show that for both types of percolation a notable effect: the crossing of the curves R versus p (with $p = p^{[H]}$ or $p = p^{[N]}$) calculated for the MPCMH and for the MNCMH. This implies that for large values of p the negative degree correlations enhance the robustness of the multiplex hypergraphs with respect to the positive correlations. To understand this phenomenon we note that close to the percolation threshold the robustness of the multiplex hypergraph is determined by the high degree nodes, that are less prone to damage in presence of positive correlations, leading to a smaller percolation threshold of MPCMH. On the contrary, for large values of p the robustness of the multiplex hypergraph, quantified by the fraction R of nodes in the giant component, is highly dependent on the low degree nodes. In particular, the role of low degree nodes is more pronounced when in each layer there is a non-negligible number of isolated nodes. In presence of positive correlations among the generalized hyperdegrees, the number of nodes isolated in both layers or connected to a small number of hyperedges (regardless of their size) is larger. As a consequence of this MNCMH have a larger fraction of nodes in the giant component than MPCMH, giving an intuition for explaining the fact that for large value of p the order parameter R becomes larger for MNCMH than for MPCMH in both for node and hyperdegree percolation in Fig. 5. This effect remains but it is strongly suppressed in absence of isolated nodes and disappears in the case in which the multiplex network is connected, i.e., there is only a single connected component.

V. HIGHER-ORDER PERCOLATION ON MULTIPLEX HYPERGRAPHS

A. The landscape of possible higher-order percolation problems

The topology of random multiplex hypergraph models allows us to explore a large variety of higher-order percolation problems. Higher-order percolation problems are characterized by illustrating cooperative phenomena where the probability that a node (or a factor node) is active depends on the presence of two or more active neighbours. These higher-order percolation problems have a highly nontrivial critical behavior and display hybrid discontinuous transitions, tricritical points, and they can even be characterized by more than one critical point as we will show in the following. Here we investigate and systematically characterize a large variety of higher-order percolation models that can be defined on multiplex hypergraphs. Inspired by the parallelism between multiplex hypergraphs and multiplex networks [6,38,40,70] we can define interlayer node interdependence in multiplex hypergraphs in which a node is active if it has at least a active neighbor on every layer of the multiplex hypergraph. This higher-order percolation is characterized by a hybrid discontinuous transition which can become a continuous transition at a tricritical point if partial interdependence is considered. However, interlayer node interdependence is not the only interdependent model that can be defined on a multiplex hypergraph. In fact, we can also consider interdependence associated to hyperedges, and assume that an hyperedge is active only when all its nodes are active. This highly non-trivial model display hybrid discontinuous transitions if the hyperedges are all involving more than two nodes. In presence of hyperedges of cardinality two (links) the transition can become continuous at a tricritical point in some cases. Note that this model is the percolation problem most directly related to the higher-order contagion problem proposed and studied in Refs. [11,27] as a nodes is activated by an hyperedge only if all the other nodes of the hyperedge are active. Another class of higher-order percolation problems is inspired by K -core percolation [36,37]. In the case of node K -core percolation a node is active if at least K of its hyperedges (of any given cardinality) are active, for hyperedge K -core percolation

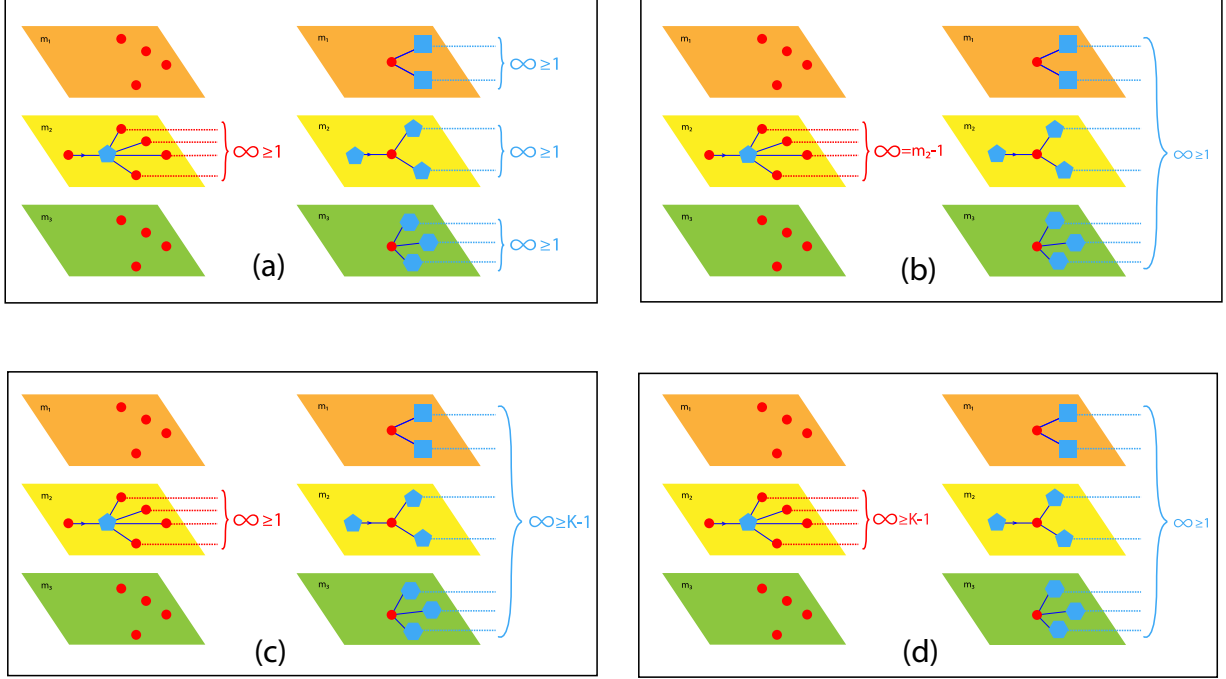

FIG. 6. Schematic representation of the equations for \hat{S}_m and for S_m determining higher-order percolation models defined on multiplex hypergraphs. Panel (a) represents node-interdependent percolation. Panel (b) represents hyperedge-interdependent percolation. Panel (c) represents Node K -core percolation. Panel (d) represents hyperedge K -core percolation.

instead an hyperedges is active if at least K of its nodes are active. In either one of these last two models the transition is discontinuous as long as $K > 2$ and the distributions $P(\mathbf{k})$ and $\hat{P}(m)$ have finite second moment. These different higher-order percolation problems are summarized in Fig. 6.

B. Interdependent node percolation

1. General framework

In analogy to interlayer dependency on multilayer networks [6,38,40,70], we consider the interlayer dependency on hypergraphs. A node in the hypergraph is active when each of its replica nodes belongs at least to one active hyperedge, i.e., the node belongs to at least one active hyperedge for each possible value of the hyperedge cardinalities m . For instance in a duplex networks representing brain regions we consider the giant component formed by brain regions (nodes) connected both in the blood vessel network and in the higher-order functional connectivity network. Similarly in social networks we consider the connected component formed by agents (nodes) connected both in the mobile phone connection networks and in some on-line or face-to-face higher-order interaction networks. In interdependent node percolation the probability \hat{S}_m that starting from a node we reach a m -factor node (m -hyperedge) that is active and the probability S_m that starting from a m -factor node (m -hyperedge) we reach a node that is active follow the recursive equations

$$\begin{aligned} \hat{S}_m &= p^{[H]} [1 - (1 - S_m)^{m-1}], \\ S_m &= p^{[N]} \sum_{\mathbf{k}} \frac{k_m}{\langle k_m \rangle} P(\mathbf{k}) \prod_{m'} [1 - (1 - \hat{S}_{m'})^{k_m - \delta_{m,m'}}]. \end{aligned} \quad (46)$$

Moreover, the order parameters \hat{R} and R indicating the fraction of active hyperedges and the fraction of active nodes, respectively, are given by

$$\begin{aligned} \hat{R} &= p^{[H]} \sum_m \hat{P}(m) [1 - (1 - S_m)^m], \\ R &= p^{[N]} \sum_{\mathbf{k}} P(\mathbf{k}) \prod_{m'} [1 - (1 - \hat{S}_{m'})^{k_m}]. \end{aligned} \quad (47)$$

As for interdependent percolation on pairwise multiplex networks, these equations lead to discontinuous (and hybrid) phase transitions. Let us indicate with Λ the maximum eigenvalue of the Jacobian matrix \mathbf{J} of the system of Eqs. (46). The critical point of the discontinuous transition corresponding to nonzero order parameters R and \hat{R} can be obtained by solving

$$\Lambda = 1 \quad (48)$$

together with Eqs. (46) and (47).

2. Independent layers

To reveal the mechanism responsible for the discontinuity of the transition, let us consider the model in the simple case in which the generalized degrees of a nodes are independent. In this case, the joint distribution $P(\mathbf{k})$ factorizes according to Eq. (29). In this limit the equations for S_m and R can be simply written as

$$\begin{aligned} S_m &= p^{[N]} (1 - G_{1,m}(1 - \hat{S}_m)) \prod_{m' \neq m} (1 - G_{0,m'}(1 - \hat{S}_{m'})), \\ R &= p^{[N]} \prod_{m'} (1 - G_{0,m'}(1 - \hat{S}_{m'})), \end{aligned} \quad (49)$$

FIG. 7. The fraction R of active nodes in interdependent node percolation is shown versus $p^{[H]}$ for a duplex multiplex hypergraph with $p^{[N]} = 1$. The layers of the duplex networks are formed by hyperedges of cardinality $m_1 = 3$ (layer 1), and $m_2 = 4$ (layer 2). Both layers have Poisson generalized degree distribution with $z_3 = z_4 = 2.5$. The inset displays the function $h(S)$ defined in Eq. (53) calculated at the critical point, i.e., for $p^{[H]} = p_c^{[H]}$.

where $G_{0,m}(x)$ and $G_{1,m}(x)$ indicate the generating functions

$$G_{0,m}(x) = \sum_{k_m} P_m(k_m)x^{k_m}, \tag{50}$$

$$G_{1,m}(x) = \sum_k \frac{k_m}{\langle k_m \rangle} P_m(k_m)x^{k_m-1}. \tag{51}$$

By choosing the generalized degree distributions $P_m(k_m)$ to be Poisson and given by Eq. (30) these equations further simplify as $G_{0,m}(x) = G_{1,m}(x)$. Therefore, we have $R = S_m = S$ for every possible value of R . Therefore, in this simple limit the order parameter $R = S$ being the largest root of the equation

$$h(S) = 0, \tag{52}$$

with the function $h(S)$ given by

$$h(S) = S - p^{[N]} \prod_m [1 - \exp[-p^{[H]} z_m (1 - (1 - S)^{m-1})]]. \tag{53}$$

For any node-interdependent multiplex hypergraph with more than one layer this equation describes a discontinuous hybrid phase transition. Indeed, Eq. (52) does not only have a trivial solution for $S = 0$ but can admit also nontrivial solutions $S > 0$. In particular, as the values of $p^{[N]}$ and $p^{[H]}$ change, the nontrivial solution emerges discontinuously when the minimum of the function $h(S)$ is achieved at a value of $S = S_c > 0$ in which $h(S) = 0$, [6] (see Fig. 7). Therefore, the critical point can be found by solving

$$h(S_c) = h'(S_c) = 0. \tag{54}$$

We can consider the model in which $p^{[N]} = 1$ or the model in which $p^{[H]} = 1$. In both models the transition is hybrid.

3. Effect of correlations between generalized degrees

Interdependent multiplex hypergraphs display a higher-order percolation transition that is significantly affected by the correlations between generalized degrees of different layers. This phenomenon is the higher-order version of the corresponding phenomenon known to occur on pairwise multiplex networks [6,16]. By considering a duplex hypergraph with tunable correlations of the generalized degrees of the two layers we observe that MPCMH are more robust than MNCMH, i.e., positive correlations between generalized degrees of different layer increase the robustness of the multiplex hypergraph. This beneficial effect of positive correlations affects the critical threshold of the higher-order percolation model, which is lower for MPCMH than for MNCMH with the same hyperdegree distributions in each of the two layers (see Fig. 8). Interestingly, for interdependent multiplex networks the beneficial effect of positive correlations remains effective for every entity of the damage. In fact, for this percolation problem, we have that also for large values of $p^{[H]}$ and $p^{[N]}$ the order parameter R for MPCMH remains always larger than the order parameter R for MNCMH. This phenomenology differs from the one observed for standard percolation (see Fig. 5). The reason for this different behavior of interdependent percolation is simple: when most of the nodes and most of the links are not initially damaged, the fraction of active nodes is maximized for positive correlations. This remains true also in presence of isolated nodes. In fact, negative correlations will imply the maximization of nodes which are isolated on at least one layer, and thus inactive, while positive correlations will minimize the number of nodes isolated in at least one layer. This simple explanation reveals why in Fig. 8 the order parameter R for MPCMH is always larger than the order parameter R for MNCMH, while we observe a crossing of the two curves for standard percolation (see Fig. 5).

4. Partial interdependence

While node-interdependency always leads to discontinuous and hybrid transitions, if partial interdependence is taken into account it is possible to observe a change of behavior at a tricritical point separating a phase in which the percolation process displays discontinuous hybrid transitions from a phase in which the process displays continuous transitions. Partial interdependence has been introduced and investigated in detail for pairwise multiplex networks [6,40,70]. Here we extend this notion to multiplex hypergraphs highlighting the similarities and differences between the two models. By partial interdependence we mean that the interdependence is not always present between the replica nodes but replica nodes are interdependent only with probability r . Therefore, for $r = 1$ we recover the node-interdependent multiplex hypergraph studied in the previous paragraph and displaying a discontinuous hybrid transition, while for $r = 0$ we recover the standard percolation model studied in Sec. III displaying a continuous transition. Let us restrict our discussion here to the simple case of independent generalized degrees with joint generalize degree distribution $P(\mathbf{k})$ given by Eq. (29). In this case, the equation for \hat{S}_m and the equation for \hat{R} remains unchanged [given by the first of Eqs. (46) and (47)]; however,

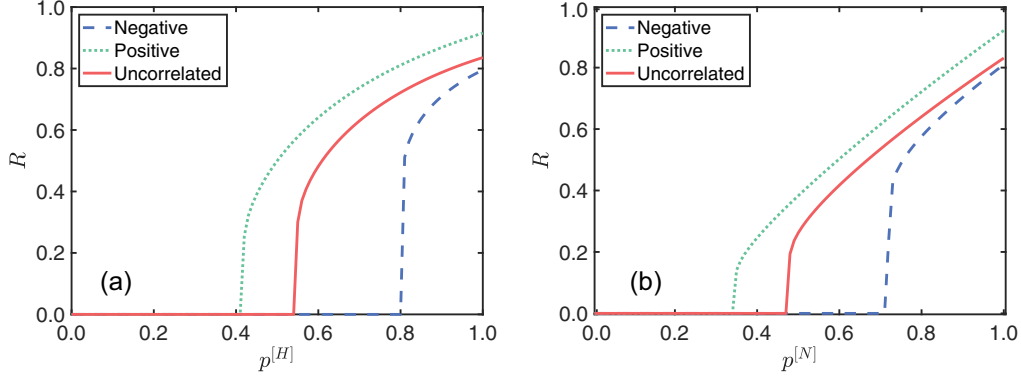

FIG. 8. The fraction of active nodes R for interdependent node percolation is plotted versus $p^{[H]}$ when $p^{[N]} = 1$ (a) and versus $p^{[N]}$ when $p^{[H]} = 1$ (b) for a MPCMH (Positive correlations) a MNCMH (Negative correlations) and for a UMH (Uncorrelated). The layers of the duplex hypergraph are formed by hyperedges of cardinality $m_1 = 3$ (layer 1), $m_2 = 4$ (layer 2), with Poisson layers of average generalized degree $z_3 = 2.5$, $z_4 = 2.5$.

the equations for S_m and R change and are given by

$$S_m = p^{[N]}(1 - G_{1,m}(1 - \hat{S}_m)) \prod_{m' \neq m} (1 - rG_{0,m'}(1 - \hat{S}_{m'})),$$

$$R = p^{[N]}(1 - G_{0,m}(1 - \hat{S}_m)) \prod_{m' \neq m} (1 - rG_{0,m'}(1 - \hat{S}_{m'})).$$

Interestingly, due to the higher-order nature of the multiplex hypergraphs these equations cannot be reduced to a single equation in the case of Poisson layers with generalized degree distribution given by Eq. (30). However, the phase diagram of the model can be investigated numerically. The phase diagram is characterized by a tricritical point separating a regime with $r < r_T$ for which we observe continuous transitions and a regime with $r > r_T$ in which we observe a discontinuous hybrid phase transition. Let us consider the case in which either nodes ($p^{[H]} = 1$, $p^{[N]} = p$) or hyperedges ($p^{[N]} = 1$, $p^{[H]} = p$) are randomly removed with probability $1 - p$. In this case, the tricritical point (r_T, p_T) can be found numerically by solving the self-consistent equations for \hat{S}_m and S_m together with

$$\Lambda = 1, \quad (55)$$

where Λ is the largest eigenvalue of the Jacobian matrix of the equations determining \hat{S}_m and S_m (see Fig. 9).

C. Interdependent hyperedge percolation

1. General framework

In this section we introduce the higher-order interdependent hyperedge percolation model. In this model an hyperedge is active only if all its nodes are active as well; moreover a node is active if at least one of its hyperedges is active. This model is here chosen because of its complementarity with the node-interdependence where a node is active if all its replica nodes are active, i.e., all its replica nodes belong to at least an active hyperedge. Interestingly, the independent hyperedge percolation problem can be related to the model of higher-order social contagion proposed in Ref. [11] and investigated on random hypergraphs in Ref. [27]. Indeed, in higher-order contagion model a node is infected if at least one of its m -hyperedges connects it to $m - 1$ infected nodes.

The interdependent hyperedge percolation model and the higher-order contagion model are closely related to each other. However, there are significant differences between the contagion model on hypergraphs and interdependent hyperedge percolation. The first one is that the percolation models are typically mapped to SIR-type dynamics while higher-order simplicial model are typically studied in the SIS settings. This difference impedes a perfect mapping between the SIS dynamics an percolation. However here we are concerned about the nature of the phase transition rather than to the details of

FIG. 9. The percolation threshold $p_c = p_c^{[H]}$ of a duplex multiplex hypergraph is plotted versus r for the interdependent node percolation process with partial interdependence. Solid line correspond to the line of continuous critical point, the dashed line corresponds to the line of discontinuous, hybrid transitions. The tricritical point separating the two lines is obtained for $r = r_T = 0.68 \dots$. The inset displays the value $R = R_c$ of the fraction of active nodes at the critical point as a function of r showing that $R_c > 0$ for $r > r_T$ indicating that the transition is discontinuous. The layers of the duplex hypergraph are formed by hyperedges of cardinality $m_1 = 3$ (layer 1), $m_2 = 4$ (layer 2), with Poisson layers of average generalized degree $z_3 = 2$, $z_4 = 2$. Here $p^{[N]}$ is set equal to one, i.e., $p^{[N]} = 1$.

the dynamics and typically the nature of the phase transition (whether the transition is continuous or discontinuous) does not depend on the choice between the SIS and SIR dynamics. The second and more significant difference is that the higher-order contagion processes admit a region of bistability in which the number of infected nodes can acquire either a larger or a smaller value depending on the initial conditions of the dynamics, while in the corresponding region of the phase diagram, the interdependent hyperedge percolation does not display bistability. Indeed, although the self-consistent equation for the order parameter admits two solutions, the order parameter R always takes the value of the largest solution of the self-consistent equations. This is due to the fact that broadly speaking percolation can be seen as an optimization problem in which one characterizes the maximum number of nodes that are connected under the conditions imposed by the combinatorics of the process.

In the hyperedge-interdependent percolation model the probability \hat{S}_m that starting from a random node we reach an m -factor node (m -hyperedge) which is active, and the probability S_m that starting from a m -factor node (m -hyperedge) we reach a node that is active are given by

$$\hat{S}_m = p^{[H]} S_m^{m-1},$$

$$S_m = p^{[N]} \sum_{\mathbf{k}} \frac{k_m}{\langle k_m \rangle} P(\mathbf{k}) \left[1 - \prod_{m'} (1 - \hat{S}_{m'})^{k_{m'} - \delta_{m,m'}} \right]. \quad (56)$$

Moreover, the order parameter \hat{R} and R indicating the fraction of active hyperedges and active nodes, respectively, are given by

$$\hat{R} = p^{[H]} \sum_m \hat{P}(m) S_m^m,$$

$$R = p^{[N]} \sum_{\mathbf{k}} \frac{k_m}{\langle k_m \rangle} P(\mathbf{k}) \left[1 - \prod_{m'} (1 - \hat{S}_{m'})^{k_{m'}} \right]. \quad (57)$$

These equations differ with respect to the equation valid for standard percolation. In particular, the equations for \hat{S}_m and \hat{R} imply that an hyperedge can be active only if all its nodes are also active. Therefore, we note that if the multiplex hypergraph contains only one layer and the layer captures only pairwise interactions, i.e., $m_1 = m = 2$ then this model reduces to standard percolation, however as long as the hypergraph contains hyperedges of cardinality $m \neq 2$ the interdependent hyperedge percolation problem differs from standard percolation. In the following paragraphs we will investigate the nature of the percolation transition and the effect of correlations among generalized degrees observed for this model.

2. Independent layers

It is instructive to investigate the critical properties of hyperedge interdependence for a multiplex hypergraph with independent layers. In this case, Eqs. (56) and (57) reduce to

$$\hat{S}_m = p^{[H]} S_m^{m-1},$$

$$S_m = p^{[N]} \left[1 - G_{1,m}(1 - \hat{S}_m) \prod_{m' \neq m} G_{0,m'}(1 - \hat{S}_{m'}) \right],$$

$$R = p^{[N]} \left[1 - \prod_m G_{0,m}(1 - p^{[H]} S_m^{m-1}) \right], \quad (58)$$

$$\hat{R} = p^{[H]} \sum_m \hat{P}(m) S_m^m,$$

where the generating functions $G_{0,m}(x)$ and $G_{1,m}(x)$ are defined in Eq. (51). By considering Poisson layers with generalized degree distribution given by Eq. (30) we observe that $S_m = R = S$ for every value of m with S satisfying

$$S = p^{[N]} \left[1 - \exp \left(-p^{[H]} \sum_m z_m S^{m-1} \right) \right]. \quad (59)$$

In the case of two-layer multiplex hypergraphs we obtain that S satisfies

$$h(S) = 0, \quad (60)$$

with

$$h(S) = S - p^{[N]} \{ 1 - \exp [-p^{[H]} (z_{m_1} S^{m_1-1} + z_{m_2} S^{m_2-1})] \}. \quad (61)$$

Let us fix the expected number of hyperedges incident to a node, regardless of their cardinality, by imposing

$$z_{m_1} + z_{m_2} = z, \quad (62)$$

and let us investigate the nature of the interdependent hyperedge percolation transition as a function of z_{m_1} . Let us start with the specific example of having two layers with $m_1 = 2$ and $m_2 = 3$. If $z_2 = z$ and $z_3 = 0$, then the multiplex hypergraph reduces to a single network, and the transition is the standard percolation transition, which occurs at a critical point characterized by satisfying

$$h(0) = h'(0) = 0. \quad (63)$$

In the other extreme case in which $z_2 = 0$ and $z_3 = z$, the multiplex hypergraph reduces to a single-layer hypergraphs including only three hyperedges. By following a well established theory of critical phenomena in simple and multiplex networks [6] we can predict that in this case the transition is discontinuous and it leads to a nonzero value $S = S_c$ for which

$$h(S_c) = h'(S_c) = 0. \quad (64)$$

These are the two limiting cases of a region of the phase space in which we observe a continuous transition and of a region of phase space in which we observe a discontinuous transition. These two regions are separated by a tricritical point observed

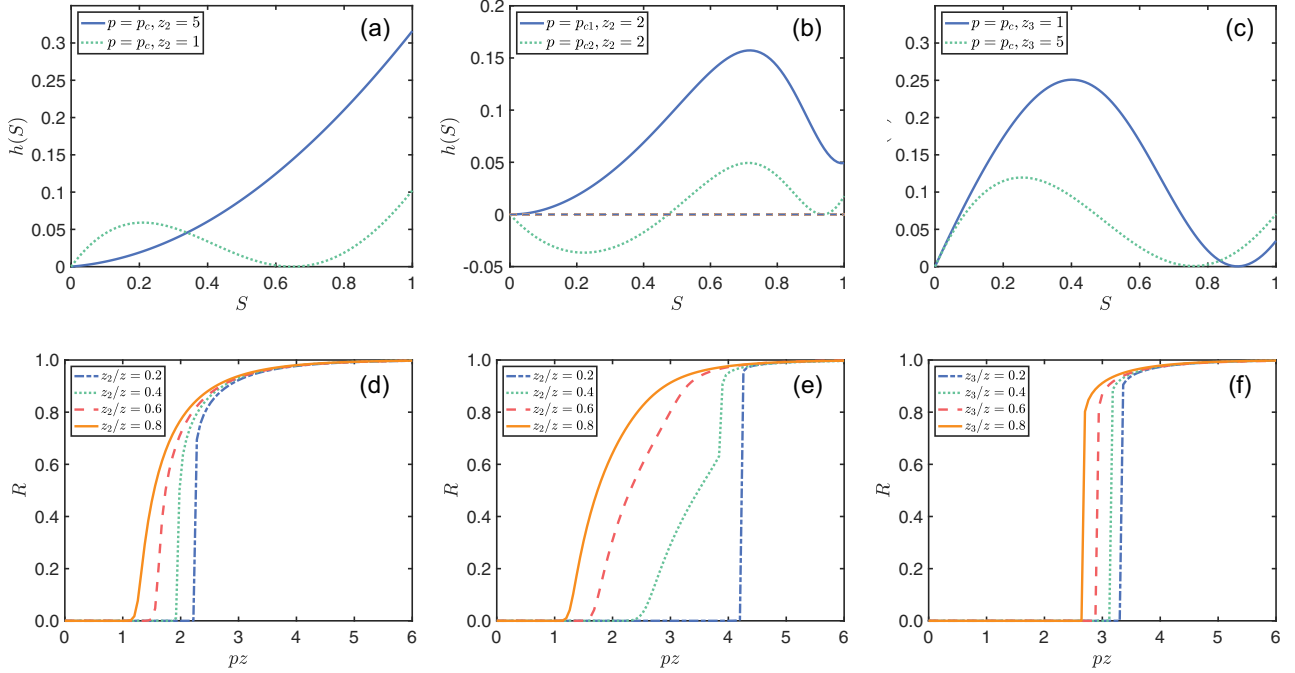

FIG. 10. The critical behavior of the interdependent hyperedge percolation process on a duplex hypergraph is investigated by plotting the function $h(S)$ defined in Eq. (52) versus S (a, c) and by displaying the the fraction of active nodes R for different values of $p = p^{[H]}$ (d, f). The duplex hypergraphs have layers with hyperedge cardinalities $m_1 = 2, m_2 = 3$ (a, d), $m_1 = 2, m_2 = 10$ (b, e), and $m_1 = 3, m_2 = 5$ (c, f). Each layer is characterized by Poisson hyperdegree distributions with average degree z_{m_1} (layer 1) and z_{m_2} (layer 2) with $z_{m_1} + z_{m_2} = z = 6$. In panel (d) we observe a continuous transitions and a discontinuous transitions occurring for different values of z_2 . In panel (e) we observe that the model can display, for the same value of z_3 , two critical points p_{c1} and p_{c2} corresponding to a continuous and discontinuous transition occurring at a nonzero value of the order parameter. In panel (f) we show that all the transitions are discontinuous.

at the value of $z_{m_1} = z_T$ that satisfies

$$h(0) = h'(0) = h''(0) = 0. \quad (65)$$

For hyperedge-interdependent percolation with $p^{[N]} = 1$ we obtain the tricritical point at

$$\begin{aligned} z_T &= \frac{2}{3}z, \\ p_T^{[H]} &= \frac{3}{2z}. \end{aligned} \quad (66)$$

For hyperedge-interdependent percolation with $p^{[H]} = 1$ we obtain the tricritical point at

$$\begin{aligned} z_T &= \sqrt{1 + 2z} - 1, \\ p_T^{[N]} &= \frac{\sqrt{1 + 2z} + 1}{2z}. \end{aligned} \quad (67)$$

As we change the values of m_1 and m_2 characterizing the two layers of the duplex multiplex network different scenarios emerges. For $m_1 > 2$ and $m_2 > 2$, the transition is always discontinuous. Interestingly, as is shown in Fig. 10(b), when $m_1 = 2$ and $m_2 > 3$ the hyperedge-interdependent percolation can display not just one but also two percolation transitions. The first transition describes the emergence of the generalized giant component and is continuous, the second transition indicates a discontinuity of the order parameter R from a nonzero value to another nonzero value. As far as we know this phenomenon has not been reported before, not even for the higher-order contagion model studied in Refs. [11,27]

but can have an interesting interpretation in that context as a sudden activation of hyperedges of larger cardinality.

3. Effect of correlations

The general equations determining hyperedge-interdependent percolation can be also used to study the effect of correlations between the generalized degrees of the replica nodes in different layers. In this case, regardless the nature of the phase transition, we observe that MPCMH display a transition threshold smaller than MNCMH, indicating that the system is able to sustain more damage. However, for small entity of the damage, and in the extreme case in which the multiplex hypergraph is not damaged, the MPCMH have a smaller giant component than the MNCMH. This phenomenon is expected as it has the same explanation of the corresponding phenomena observed and discussed in Sec. III for the case of standard percolation (see Fig. 11).

D. Node K -core percolation

In this section we propose the K -core node percolation on random multiplex hypergraphs. This model is a higher-order percolation process that generalizes K -core percolation of single pairwise networks to the multiplex hypergraphs. In K -core node percolation a node is active if has at least K active neighbours. In K -core node percolation defined on a multiplex hypergraph, a node is active if it belongs at least to K active hyperedges regardless of their cardinality. Physical motivations for this dynamics are not lacking as this is a

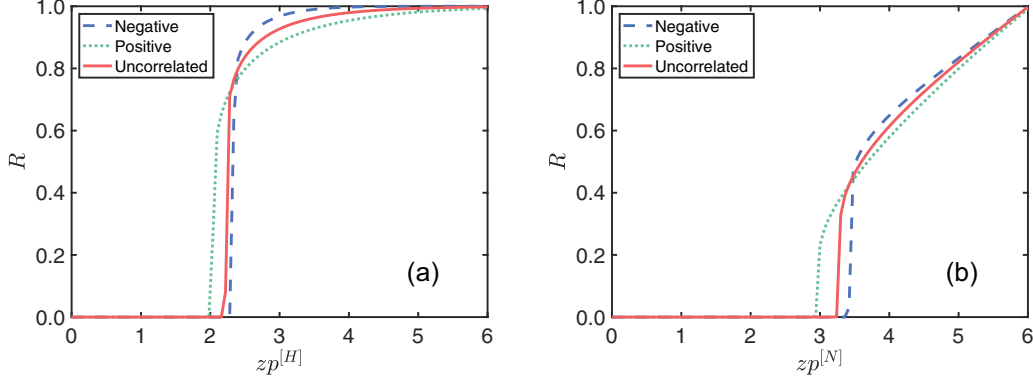

FIG. 11. The fraction of active nodes R in the interdependent hyperedge percolation is plotted versus $p^{[H]}$ when $p^{[N]} = 1$ (a) and versus $p^{[N]}$ when $p^{[H]} = 1$ (b) for a MPCMH (Positive correlations) a MNCMH (Negative correlations) and for a UMH (Uncorrelated). The layers of the duplex hypergraph are formed by hyperedges of cardinality $m_1 = 2$ (layer 1), $m_2 = 3$ (layer 2), with Poisson layers of average generalized degree $z_2 = 4.8$, $z_3 = 1.2$ and $z = z_2 + z_3 = 6$.

fundamental example of cooperative model in the class of threshold models [71,72] that are known to determine fundamental aspects of contagion and avalanche dynamics. The probability \hat{S}_m that starting from a node we reach an m -factor node (m -hyperedge) that is active and the probability S_m that starting from a m -factor node (m -hyperedge) we reach a node that is active follow the recursive equations

$$\begin{aligned} \hat{S}_m &= p^{[H]}[1 - (1 - S_m)^{m-1}], \\ S_m &= p^{[N]} \sum_{\mathbf{k}}' \frac{k_m}{\langle k_m \rangle} P(\mathbf{k}) \left[1 - \sum_{q=0}^{K-2} B_q(\mathbf{k}) \right], \end{aligned} \quad (68)$$

where $\sum_{\mathbf{k}}'$ indicates the sum over \mathbf{k} such that

$$\sum_m k_m \geq K. \quad (69)$$

Here $B_q(\mathbf{k})$ is given by

$$B_q(\mathbf{k}) = \sum_{\{q_{m'}\}}'' \prod_{m'} \left[\binom{k'_m - \delta_{m,m'}}{q_{m'}} \hat{S}_{m'}^{q_{m'}} (1 - \hat{S}_{m'})^{k'_m - \delta_{m,m'} - q_{m'}} \right],$$

where $\sum_{\{q_{m'}\}}''$ indicates the sum over of $\{q_{m'}\}$ such that

$$\sum_{m'} q_{m'} = q. \quad (70)$$

The order parameters R and \hat{R} expressing the fraction of nodes (R) and the fraction of hyperedges (\hat{R}) in the node K -core are given by

$$\begin{aligned} \hat{R} &= p^{[H]} \left[1 - \sum_m \hat{P}(m) (1 - S)^{m-1} \right], \\ R &= p^{[N]} \left[1 - \sum_{\mathbf{k}}' P(\mathbf{k}) \sum_{q=0}^{K-1} D_q \right], \end{aligned} \quad (71)$$

with D_q given by

$$D_q = \sum_{\{q_{m'}\}}'' \prod_{m'} \left[\binom{k'_m}{q_{m'}} \hat{S}_{m'}^{q_{m'}} (1 - \hat{S}_{m'})^{k'_m - q_{m'}} \right]. \quad (72)$$

It follows that the equations for node K -core percolation reduce to standard K -core percolation if the multiplex hypergraph is formed by a single layers encoding for hyperedges of cardinality $m = 2$ (i.e., links). For node K -core percolation, like for node K -core percolation on pairwise networks [36,37], we observe that the percolation transition is discontinuous and hybrid as long as $K > 2$ provided that the generalized degree distributions have finite second moment (see Fig. 12).

FIG. 12. The fraction R of active nodes for the node K -core percolation on duplex hypergraphs with independent Poisson layers is shown versus the probability of retaining a hyperedge $p^{[H]} = p$. The duplex hypergraph includes $N = 10^4$ nodes and has layers formed by hyperedges of cardinality $m_1 = 4$ and $m_2 = 5$ with independent Poisson generalized hyperdegree distributions with average $z_4 = z_5 = 2$. Here $p^{[N]}$ is fixed to the constant value $p^{[N]} = 1$. The node K -core percolation is discontinuous for $K > 2$.

E. Hyperedge K -core percolation

Hyperedge K -core percolation is here defined as a higher-order percolation process occurring on multiplex hypergraphs in which a hyperedge is active only if at least K (with $K \geq 2$) nodes belonging to it are also active. This model interpolates between percolation and interdependent percolation. Therefore, it describes the physical scenario in which a node is activated only if a critical number of nodes belonging to the same hyperedge is activated and can describe another variation of contagion models or threshold models [71,72]. In this case, the probability \hat{S}_m that starting from a node we reach a m -factor node (m -hyperedge) that is active and the probability S_m that starting from a m -factor node (m -hyperedge) we reach a node that is active are given by

$$\hat{S}_m = \begin{cases} p^{[H]} [1 - \sum_{q=0}^{K-2} \hat{B}_q(m)] & \text{for } m \geq K \\ 0 & \text{for } m < K \end{cases},$$

$$S_m = p^{[N]} \left[1 - \sum_{\mathbf{k}} \frac{k_m}{\binom{k}{m}} P(\mathbf{k}) \prod_{m'} (1 - \hat{S}_{m'})^{k_{m'} - \delta_{m,m'}} \right], \quad (73)$$

where $B_q(m)$ can be expressed as

$$\hat{B}_q(m) = \binom{m-1}{q} (S_m)^q (1 - S_m)^{m-1-q}. \quad (74)$$

Similarly we can define the order parameters R and \hat{R} indicating the fraction of nodes and hyperedge that are active as

$$\hat{R} = p^{[H]} \sum_{m \geq K} \hat{P}(m) \left[1 - \sum_{q=0}^{K-1} \binom{m-1}{q} S_m^q (1 - S_m)^{m-1-q} \right],$$

$$R = p^{[N]} \left[1 - \sum_{\mathbf{k}} P(\mathbf{k}) \prod_{m'} (1 - \hat{S}_{m'})^{k_{m'}} \right]. \quad (75)$$

For hyperedge K -core percolation like for K -core percolation on pairwise networks [36,37], we observe that the percolation transition is discontinuous and hybrid as long as $K > 2$ provided that the distribution $\hat{P}(m)$ has finite second moment (see Fig. 13).

VI. CONCLUSIONS

In this paper we have provided a comprehensive framework to study standard and higher-order percolation on random multiplex hypergraphs. Random multiplex hypergraphs are a natural generalization of random hypergraphs where the hyperedges of different cardinality are associated to different layers of the multiplex. This modeling framework is very comprehensive and is here used to investigate the rich interplay between the topology of hypergraphs and the properties of standard and higher-order percolation defined on these structures. We reveal how interlayer correlations among the generalized degree of replica nodes can affect the critical properties of standard percolation. In particular, we show that close to the percolation transition positive correlations enhance the robustness of multiplex hypergraphs while when the initial damage is minor, negative correlations can be beneficial to network robustness. We show how the multi-

FIG. 13. The fraction R of active nodes for the hyperedge K -core percolation on duplex hypergraphs with independent Poisson layers is shown versus the probability of retaining a hyperedge $p^{[H]} = p$. The duplex hypergraph includes $N = 10^4$ nodes and has layers formed by hyperedges of cardinality $m_1 = 4$ and $m_2 = 5$ with independent Poisson generalized hyperdegree distributions with average $z_4 = z_5 = 2$. Here $p^{[N]}$ is fixed to the constant value $p^{[N]} = 1$. The transition is discontinuous for $K > 2$.

layer nature of multiplex hypergraphs can be exploited to define a number of higher-order percolation processes. In particular, we propose two models generalizing interdependent percolation in multiplex networks and contagion model in hypergraphs (the interdependent node and the interdependent hyperedge percolation) and two models generalizing K -core percolation to hypergraphs (the node K -core and hyperedge K -core percolation). These models are here shown to display a rich phenomenology including discontinuous hybrid phase transitions, tricritical points, and multiplex phase transitions together with nontrivial effects due to the interlayer correlations among the generalized degrees.

Although our aim is to provide a comprehensive view of the possible higher-order percolation processes on random multiplex hypergraphs we are aware that the processes investigated in this work are not exhaustive of the many relevant percolation processes that can be defined on these structures. We hope that this work can generate further interest in the interplay between the structure of higher-order networks and their dynamics and that the revealed properties of percolation on multiplex hypergraphs can open new insights also for the study of other dynamical processes such as epidemic spreading and social contagion.
