Electrostatic two-stream instabilities play essential roles in an electrostatic collisionless shock formation. They are a key dissipation mechanism and result in ion heating and acceleration. Since the number and energy of the shock-accelerated ions depend on the instabilities, precise identification of the active instabilities is important. Two-dimensional particle-in-cell simulations in a multicomponent plasma reveal ion reflection and acceleration at the shock front, excitation of a longitudinally propagating electrostatic instability due to a nonoscillating component of the electrostatic field in the upstream region of the shock, and generation of up- and down-shifted velocity components within the expanding-ion components. A linear analysis of the instabilities for a C_2H_3Cl plasma using the one-dimensional electrostatic plasma dispersion function, which includes electron and ion temperature effects, shows that the most unstable mode is the electrostatic ion-beam two-stream instability (IBTI), which is weakly dependent on the existence of electrons. The IBTI is excited by velocity differences between the expanding protons and carbon-ion populations. There is an electrostatic electron-ion two-stream instability with a much smaller growth rate associated with a population of protons reflecting at the shock. The excitation of the fast-growing IBTI associated with laser-driven collisionless shock increases the brightness of a quasimonoenergetic ion beam.

I. INTRODUCTION

In unmagnetized plasmas, a relative drift between two plasma populations results in the excitation of electrostatic two-stream instabilities. In the case of cold ion beams, the electrostatic ion-beam two-stream instability (IBTI), which is a resonant instability driven by slow- and fast-ion beams, is excited [1]. When a relative drift exists between electrons and ions, the Buneman instability is excited [2]. By adding electrons with Maxwellian velocity-distribution function to the cold drifting-ions, the system is possibly unstable to the electrostatic ion-ion acoustic instability (ion-ion AI) and the electrostatic electron-ion acoustic instability (electron-ion AI) [1,3,4], in addition to IBTI and Buneman instability [1]. The electron-ion AI and ion-ion AI are excited in the electron background. Whereas the electron-ion AI is excited by the relative drift between electrons and ions, the ion-ion AI is excited when the relative drift between ion species is present. Therefore, in a multispecies ion plasma with relative drifts between ion species, both the electron-ion AI and ion-ion AI can be excited in addition to IBTI. It is well known that the growth rates of the electron-ion AI and ion-ion AI are much smaller than that of IBTI [1,3].

Akimoto and Omidi [5] have conducted a linear analysis to study a broad-band electrostatic noise excited by an ion beam in the Earth's magnetotail, and shown that the broad-band electrostatic noise can be explained by the presence of the ion-ion AI and electron-ion AI. Wahlund *et al.* [6] have revealed that the observation of enhanced ion-acoustic line spectra in the topside auroral ionosphere results from the ion-ion AI or IBTI in a multicomponent (H^+, O^+, and NO^+) plasma. The ion-ion AI and IBTI have been observed in ion beam-plasma [7–9] and laser-plasma [10–13] experiments.

Electrostatic two-stream instabilities play essential roles in collisionless shock formation as a dissipation mechanism, which results in ion acceleration and heating mechanism. Two-dimensional (2D) particle-in-cell (PIC) simulations were conducted to investigate the ion-ion AI and IBTI in collisionless shocks [1,4,14–16]. Ohira and Takahara [1] have investigated at the foot region of a collisionless shock with a very high Mach-number over 100, the fastest-growing mode is not the electron-ion AI but the highly oblique ion-ion AI and IBTI excited by the shock-reflected ions. Sarri *et al.* [15] have shown that the nearly transverse ion-ion AI is excited by the reflected protons from the laser-driven electrostatic collisionless shock. This work provides details of electrostatic two-stream instabilities associated with laser-driven collisionless shocks that occur in a multicomponent plasma.

Recently, we reported a laser-driven electrostatic collisionless shock acceleration [17–19] of ions in multicomponent plasmas and excitation of electrostatic ion two-stream insta-

bilities [20]. Hereafter, we refer to this work as Paper I. The electrostatic collisionless shock acceleration has been demonstrated in the laboratory using a 10-μm wavelength CO_2 laser and a near-critical density gas target [21]. Several experiments on collisionless shock acceleration have been carried out in the last few years [22–27]. For medical applications, such as cancer therapies [28], quasimonoenergetic ions are preferred. A laser-driven collisionless-shock-acceleration is a candidate ion source as the weak sheath field results in a quasimonoenergetic ion beam [29].

In Paper I, Kumar *et al.* demonstrated using PIC simulations the possibility of producing high-flux and low energy-spread proton beams in a multicomponent C_2H_3Cl plasma. The target consists of a tailored density profile with an exponentially decreasing density with 30-μm scale length on the rear side. This results in a uniform electrostatic sheath field E_{TNSA} ahead, upstream, of the shock. Expansion of ions under E_{TNSA} results in relative drifts between slower-moving C ions with lower average charge-to-mass ratio $\langle Z \rangle / \langle A \rangle = 0.5$ and faster-moving protons with higher $\langle Z \rangle / \langle A \rangle = 1$. It was shown that the development of the longitudinal electrostatic ion two-stream instabilities play important roles in multicomponent plasmas and the associated ion acceleration process. By using the cold-ion approximation and ignoring the electrons, it was shown that two electrostatic ion two-stream instabilities or two IBTIs can be excited: One is the heavy-ion electrostatic ion two-stream instability, which is excited between the expanding proton and C-ion populations. This instability occurs in a multicomponent plasma as ion components have different $\langle Z \rangle / \langle A \rangle$ ratios, such as in a CCl_2 plasma with fully ionized C^{6+} ($\langle Z \rangle / \langle A \rangle = 0.5$) and Cl^{10+} ($\langle Z \rangle / \langle A \rangle = 0.28$) ions as shown in Fig. 7(b) of Paper I. The other is reflected-proton electrostatic ion two-stream instability, which is excited between the reflected and expanding proton populations associated with the shock. In this analysis, the growth rate and the wave number of the most unstable modes of the instabilities are derived from an analytical model with two cold-ion populations without a treatment of the electron population.

In Ref. [30], we observed two electrostatic collisionless shocks at two distinct longitudinal positions when driven with laser at normalized laser vector potential $a_0 > 10$. Moreover, these shocks, associated with protons and carbon ions accelerate ions to different velocities in an expanding upstream with higher flux than in a single-component hydrogen or carbon plasma. A broadening upwards of the C^{6+}-ion velocity distribution, which is important to increase the number of the accelerated C^{6+} ions, is predicted to result from the heavy-ion electrostatic ion two-stream instability [30].

In this paper, we report on the identification of electrostatic two-stream instabilities associated with laser driven electrostatic collisionless shocks in a multicomponent C_2H_3Cl plasma investigated using 2D PIC simulations. These PIC simulations use the normalized laser vector potential $a_0 = 3.35$, as discussed in Paper I, to investigate the electrostatic ion two-stream instability. At this laser intensity, only a proton shock is excited. A linear analysis of the instabilities for a C_2H_3Cl plasma, with electrons, protons, C and Cl ions, is carried out using the one-dimensional electrostatic plasma dispersion function for unmagnetized collisionless plasmas

including ion temperature effect to identify the electrostatic ion two-stream instability. We use plasma parameters, such as temperatures, densities, and drift velocities for all the species of particles, obtained from the PIC simulations. To identify the instabilities, we start the linear analysis from the case of cold ions and ignoring the role of electrons, in which IBTI can be excited, and artificially removing some ion species. This is extended to cold ions and hot electrons, in which the electron-ion AI and ion-ion AI are excited. Finally, finite-temperature ions are included to understand the influence of the ion Landau damping.

The paper is structured as follows: In Sec. II, we discuss the EPOCH [31] 2D PIC calculations in a multicomponent C_2H_3Cl plasma. We describe the temporal evolution of the proton phase space and the broadening of upstream expanding-proton distribution. Section III outlines a linear instability analysis using data from the numerical simulations. This section is divided into four parts and examines the instabilities for cold ions without electrons (Sec. III A), cold ions with hot electrons (Sec. III B), warm ions with hot electrons (Sec. III C), and in Sec. III D we identify the observed instabilities. The results of the numerical simulations and the linear analysis are discussed in Sec. IV and summarized in Sec. V.

II. PARTICLE-IN-CELL SIMULATION IN A MULTICOMPONENT PLASMA

The EPOCH calculations are conducted with the same parameters as described in Paper I. The simulation box is 300 μm × 6 μm in size and composed of 9000 × 180 cells along the *x* and *y* axis, respectively, with 30 particles per cell. The skin depth is resolved by 2.7 cells, and the electron-proton mass ratio of 1836 is used. The boundary conditions are open in the *x* direction and periodic in the *y* direction for both fields and particles. The laser pulse is modeled as the electromagnetic plane wave with linear *p*-polarization along the *y* axis and propagates in the *x* direction. The normally incident laser pulse with infinite spot size has a Gaussian temporal profile with 1.5-ps full width at half-maximum. The peak intensity is 1.4×10^{19} W/cm^2 ($a_0 = 3.35$). The laser pulse interacts with a fully ionized plasma density at $x = 40$ μm. We use a C_2H_3Cl plasma with a longitudinal (*x* direction) density profile consisting of an exponentially increasing 5-μm scale length laser-irradiated front region, 5-μm uniform central region, and an exponentially decreasing profile with 30-μm scale-length rear region as the back of the target. To avoid boundary effects, the simulations use 40-μm ($x = 0$–40 μm) and 100-μm ($x = 200$–300 μm) vacuum regions at the front and rear of the target, respectively. Details of the simulations including the target density profiles at $a_0 = 3.35$ are given in Kumar *et al.* [20,30]. The maximum electron density is fixed at the relativistic critical density $a_0 n_{cr}$, where $n_{cr} = 1.12 \times 10^{21}$ cm^{-3} is the critical plasma density for the 1.053-μm wavelength laser used in these simulations. The charge states Z of protons, C ions, and Cl ions are 1, 6, and 15, respectively. Cl (atomic number 17) is ionized to the He-like ion state, Cl^{15+}. The three ions have average charge-to-mass ratios $\langle Z \rangle / \langle A \rangle$ of 1, 0.5, and 0.42, respectively. The corresponding ion density for each material is calculated

from the quasineutral plasma condition. Initial temperatures of particles are 500 eV for all species.

To accelerate the ions via the collisionless shock acceleration mechanism, the potential energy at the shock front must be larger than the kinetic energy of the upstream expanding ions in the shock rest frame. In other words, the electrostatic potential at the shock front must satisfy the following conditions [32], $Ze\phi \geqslant \frac{1}{2}Am_p(V_{sh}^i - v_0^i)^2$. Here ϕ, V_{sh}^i, and v_0^i are the electrostatic potential, the shock velocity, and the particle velocity, superscript i represents the different ion species. The lower threshold (v_L^i) in v_0^i for ion reflection via the collisionless shock acceleration mechanism is $v_L^i = V_{sh}^i - \sqrt{2(Z_i/A_i)e\phi/m_p}$. Namely the reflection condition is given by $v_L^i \leqslant v_0^i \leqslant V_{sh}^i$ [20,30]. This equation represents the lower v_L^i and upper V_{sh}^i bounds in v_0^i for ion reflection. Therefore, all ions with a velocity component in between v_L^i and V_{sh}^i are reflected by the shock potential to a velocity $V_{sh}^i + \sqrt{2(Z_i/A_i)e\phi/m_p} = 2V_{sh}^i - v_L^i$. For protons $Z_i = A_i = 1$ and neglecting the superscript i, $v_L = V_{sh} - \sqrt{2e\phi/m_p}$.

Figure 1 represents the temporal evolution of the proton phase space and the corresponding velocity spectrum taken at $\Delta x = 3$ μm shown by the vertical lines on the phase space. A significantly large number of protons satisfy the reflection condition at all times. Therefore, a large fraction of protons is accelerated via the collisionless shock acceleration mechanism.

Figure 2 shows the temporal evolution of the upstream expanding-proton velocity distribution taken at $\Delta x = 3$ μm in the upstream region of a C_2H_3Cl plasma, which is replotted from Fig. 1. The broadening of the upstream expanding-protons in a multicomponent plasma is caused by the two-stream instability as explained previously and in Paper I. The width of the velocity distribution in the x direction increases with time as shown in Figs. 2(a)–2(c). The shape of the velocity spectrum can be described by using three 1D shifted-Maxwellian distributions for all times, and examples are shown in Fig. 2 at $t = 2.0$, 3.0, and 4.0 ps.

Temporal evolution of the peak number density dN/dv, velocity v at the peak number density, and the proton temperature T_P of the three fitted-Maxwellian distributions of the upstream expanding protons are represented in Figs. 3(a), 3(b), and 3(c), respectively. In Fig. 3(a), the dN/dv^L, dN/dv^M, and dN/dv^H denote number densities at the peaks of the fitted-Maxwellian distributions for the low-, medium-, and high-velocity components of the distributions in the upstream region. It is clear from Fig. 3, at $t = 1.50$ ps of the laser peak, a large number of protons are in the low-velocity component, a small number of protons are in the high-velocity component, and their temperatures are nearly the same ($T_P^H \simeq T_P^L \simeq 0.01$ MeV). After the laser peak has passed, protons in the upstream region are accelerated by a uniform sheath electric field E_{TNSA}, and the peak velocities of three Maxwellian components keep increasing with time as shown in Fig. 3(b). At $t = 1.75$ ps, the third Maxwellian distribution component with a very low number density and low temperature starts to appear. Temperatures of three velocity components start increasing at $t = 2.0$ ps, and T_P^L and T_P^H remain the same with 0.06 and 0.048 MeV, respectively, after $t = 2.75$ ps, while T_P^M keeps

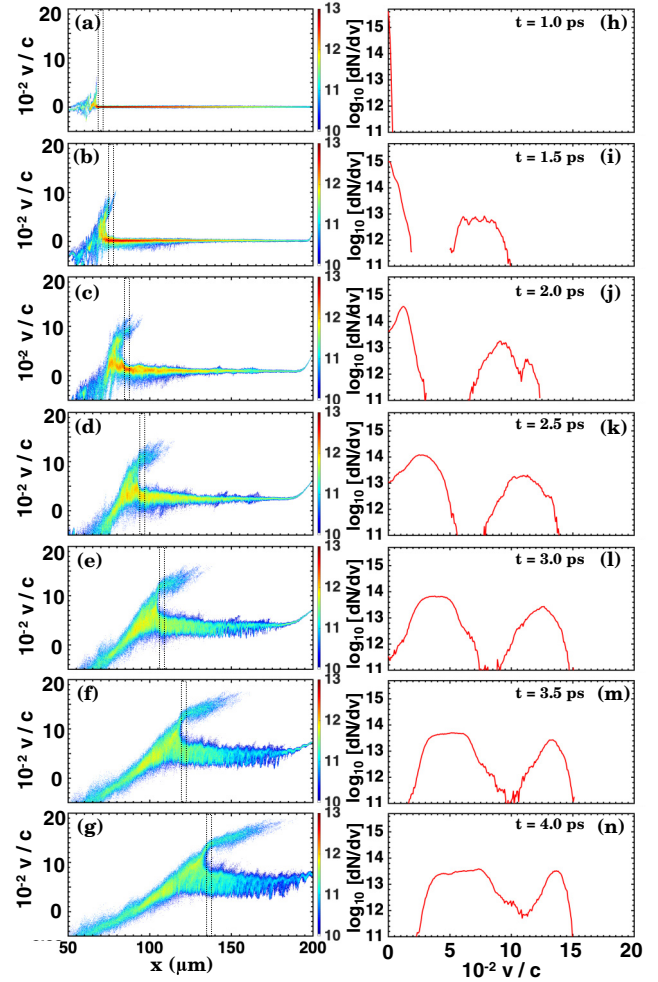

FIG. 1. The temporal evolution of (a)–(g) proton phase space and (h)–(n) their corresponding velocity spectrum taken at $\Delta x = 3$ μm in the upstream region (shown by vertical dotted lines in phase space) in a C_2H_3Cl plasma. The color scale shows the number of ions in a log scale.

increasing as shown in Fig. 3(c). These increments in T_P^L and T_P^H show a similar trend as that in the electron temperature T_e, this is illustrated in Fig. 12(c) of the Appendix, with a delay of $\simeq 1$ ps, that is T_e and T_P start increasing at 1 and 2 ps, respectively. By $t = 2.75$ ps peak values of dN/dv^L, dN/dv^M, and dN/dv^H become nearly equal, and they are nearly constant later as shown in Fig. 3(a).

Paper I reports on the formation of a high-energy tail in expanding C^{6+} ions in addition to the heating of expanding protons. This heating of expanding protons and C^{6+} ions result from the excitation of longitudinally propagating electrostatic two-stream instabilities.

III. LINEAR ANALYSIS OF INSTABILITIES

In Paper I, using an approximated dispersion relation we have shown that the excitation of electrostatic instability leads to the broadening of upstream expanding-proton distribution in the multicomponent plasma. The PIC simulations in
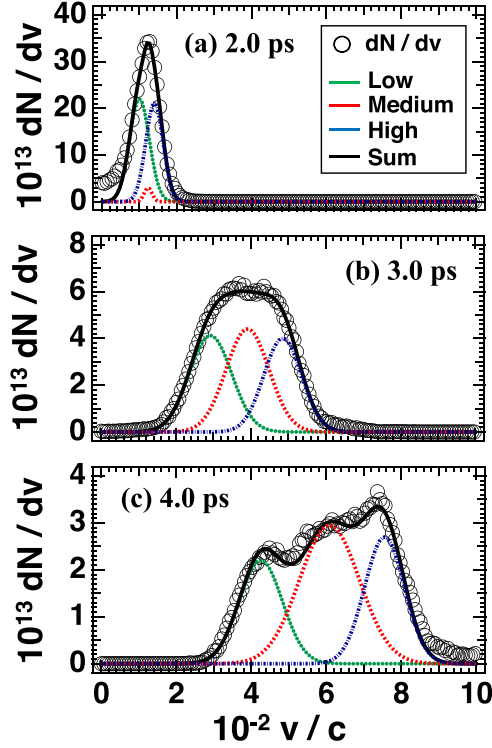

FIG. 2. The velocity spectrum (open circles) of the upstream expanding protons taken at $\Delta x = 3$ μm of the upstream region in a C_2H_3Cl plasma at (a) $t = 2.0$, (b) 3.0, and (c) 4.0 ps, which is replotted from Fig. 1. Note that the y axis is in the linear scale. A sum (black line) of the three 1D shifted-Maxwellian distributions [low (green line), medium (red line), and high (blue line) velocity components] are used to fit the upstream expanding protons.

FIG. 3. Temporal evolution of the upstream expanding protons taken at $\Delta x = 3$ μm of the upstream region in a C_2H_3Cl plasma. (a) Peak number density dN/dv, (b) velocities v/c at the peak number density, and (c) proton temperature T_P of the low (L), medium (M), and high (H) velocity components of the fitted 1D shifted-Maxwellian distributions.

Paper I show that the propagation direction of the electrostatic instability is longitudinal to the flow direction (x direction). However, the previous analysis did not take into account thermal effects. In this section, to clarify the physical picture of the instability, we carry out a linear analysis of the longitudinal electrostatic instability for a C_2H_3Cl plasma using the one-dimensional electrostatic plasma dispersion function [1].

For unmagnetized collisionless plasmas, the electrostatic dispersion relation is expressed as [1]

$$1 + \sum_{s=e+i} \frac{2\omega_{ps}^2}{k^2 v_{ths}^2}[1 + \xi_s Z(\xi_s)] = 0, \qquad (1)$$

$$Z(\xi_s) = \frac{1}{\sqrt{\pi}} \int_{-\infty}^{+\infty} \frac{e^{-z^2}}{z - \xi_s} dz, \qquad (2)$$

$$\xi_s = \frac{\omega - kv_s}{kv_{ths}}, \qquad (3)$$

where s is electron (e) and ion species (i); ω is the frequency; k is the wave number in the x direction; ω_{ps}, v_s, and $v_{ths} = \sqrt{2T_s/m_s}$ are the plasma frequency, drift velocity, and thermal velocity of particle species s; and $Z(\xi_s)$ is the plasma dispersion function [33]. In the calculation, electrons ($s = e$), expanding C^{6+} ions ($s = C$), expanding Cl^{15+} ions ($s = Cl$), expanding protons ($s = $ P-exp), and reflected

protons ($s = $ P-ref) are included. The electrostatic dispersion relation [Eq. (1)] can be numerically solved.

When $T_i = 0$, $v_e = 0$, and $\xi_e \gg 1$, Eq. (1) is reduced to

$$1 - \frac{\omega_{pe}^2}{\omega^2 - k^2 v_{the}^2} = \sum_i \frac{\omega_{pi}^2}{(\omega - kv_i)^2}. \qquad (4)$$

On the other hand, when $T_i = 0$, $v_e = 0$, and $\xi_e \ll 1$, Eq. (1) is reduced to

$$1 + \frac{1}{k^2 \lambda_{De}^2} = \sum_i \frac{\omega_{pi}^2}{(\omega - kv_i)^2}, \qquad (5)$$

where, λ_{De} is the electron Debye length. Equation (5) is rewritten as,

$$1 = \sum_i \frac{1}{1 + k^2 \lambda_{De}^2} \frac{(n_i/n_e)k^2(T_e/m_i)}{(\omega - kv_i)^2}. \qquad (6)$$

When $1/(k^2 \lambda_{De}^2) = 0$, that is equivalent to no electron effect or $n_e = 0$, Eq. (5) is reduced to

$$1 = \sum_i \frac{\omega_{pi}^2}{(\omega - kv_i)^2}. \qquad (7)$$

Table I summarizes all the plasma parameters used in the analysis. For electrons, relativistic plasma frequency of ω_{pe}

TABLE I. Densities, plasma frequencies, temperatures, drift velocities, and relative drift velocities to Cl^{15+} of particle species s used in the linear analysis of the electrostatic two-stream instability for a C_2H_3Cl plasma. Electrons ($s = e$), expanding C^{6+} ions ($s = C$), expanding Cl^{15+} ions ($s = Cl$), expanding protons ($s = P$-exp), and reflected protons ($s = P$-ref) are included. These parameters are derived from the 2D PIC simulations at $t = 4.0$ ps shown in the previous section.

In the following, we show the results of linear analysis of the electrostatic instability excited in a multicomponent C_2H_3Cl plasma by solving the dispersion relation [Eq. (1)]. We represent three cases from the simplest to something more realistic: (A) cold ions without electrons, (B) cold ions with hot electrons, and (C) finite-temperature ions. In case A, the dispersion relation is approximated by Eq. (7), which corresponds to the cold ion-beam interaction, and the excitation of the electrostatic ion-beam two-stream instability (IBTI) is shown. In case B, the dispersion relation is approximated by Eqs. (5) and (6), and the excitation of the electrostatic electron-ion acoustic instability (electron-ion AI) and the electrostatic ion-ion acoustic instability (ion-ion AI) is displayed. In case C, the full dispersion relation [Eq. (1)] is used, and the ion Landau damping effect and the ion-temperature dependence of the instability threshold are displayed. Finally, we identify the instabilities observed in the PIC simulation.

FIG. 4. Results of the linear analysis of the electrostatic two-stream instability for a C_2H_3Cl plasma when $n_e = 0$ and $T_i = 2 \times 10^{-5}$ MeV. [(a) and (c)] The imaginary part (Im $[\omega]/\omega_{pe}$) and [(b) and (d)] real part (Re $[\omega]/\omega_{pe}$) of normalized frequencies versus the normalized wave number in the x direction (kv_0/ω_{pe}, where $v_0 = v_{P-ref} - v_{Cl}$). Panels (a) and (b) [(c) and (d)] are plotted for $kv_0/\omega_{pe} < 5$ [$kv_0/\omega_{pe} < 0.35$]. The thin red, blue, green, and orange lines in (b) and (d) are the fast and slow Ref-P, Exp-P, Exp-C, and Cl modes, respectively.

The dispersion relations are expressed in a rest frame where the drift velocity of expanding Cl^{15+} ions (v_{Cl}) is zero.

A. Cold ($T_i = 2 \times 10^{-5}$ MeV) ions and without electrons: Excitation of the electrostatic IBTI

First, we show the results of linear analysis for cold ions and no electron effects. By applying this approximation [$1/(k^2\lambda_{De}^2) = 0$ or equivalent to $n_e = 0$], the dispersion relation is reduced to Eq. (7). The resultant instability is the IBTI [1]. This is a resonance instability driven by slow- and fast-ion beams with relative drifts between ion species. The electron effect is negligible because of the large electron Debye length.

Figures 4(a) and 4(b) show, respectively, normalized imaginary part or growth rate (Im $[\omega]/\omega_{pe}$) and real part (Re $[\omega]/\omega_{pe}$) of the instability frequency versus normalized wave number in the x direction (kv_0/ω_{pe}) when $T_i = 2 \times 10^{-5}$ MeV and $n_e = 0$. Here ω_{pe} is the electron plasma frequency, and v_0 is the drift velocity v_{P-ref} of reflected protons in a rest frame where the drift velocity v_{Cl} of expanding Cl^{15+} ions is zero ($v_0 = v_{dP-ref} = v_{P-ref} - v_{Cl} = 0.109c$). When $T_i = 2 \times 10^{-5}$ MeV, the ion temperature effect is negligible, and the dispersion relation is reduced to Eq. (7). Figures 4(c) and 4(d) are replotted from Figs. 4(a) and 4(b), respectively, for $kv_0/\omega_{pe} < 0.35$. As shown in Figs. 4(b) and 4(d), when no interactions occur among these modes, i.e., at $kv_0/\omega_{pe} > 4$, we find no imaginary roots and eight real roots; the slow and fast modes of the reflected protons ($\omega = kv_{dP-ref} \pm \omega_{pP-ref}$, where $+$ and

− correspond to the fast and slow modes, respectively), the expanding protons ($\omega = k v_{dP-exp} \pm \omega_{pP-exp}$), the expanding C-ions ($\omega = k v_{dC} \pm \omega_{pC}$), and Cl-ions ($\omega = \pm \omega_{pCl}$, where $v_{dCl} = 0$). The plasma frequencies (ω_{ps}), drift velocities (v_s), and relative drift velocities to Cl^{15+} ions (v_{ds}) are summarized in Table I. We used ω_{pe} value shown in Table 1 for the normalization.

Two-stream instabilities become unstable when the slow and fast modes interact with each other, and two complex roots appear. In other words, we have solutions of $\omega = Re[\omega] \pm i Im[\omega]$. This is clearly shown in Fig. 4 where three unstable roots with the maximum growth rate γ_m at $k_m v_0 / \omega_{pe} \simeq 0.085, 0.17$, and 2.2 are excited. Here, the k_m represents the k value at the maximum growth rate γ_m. They are unstable slow modes excited between the slow reflected-proton (Ref-P) and fast expanding-proton (Exp-P) modes, the slow Exp-P and fast expanding-C-ion (Exp-C) modes, and the slow Exp-C and fast Cl-ion (Cl) modes from the small to large k, and we call these three unstable modes as Ref-P, Exp-P, and Exp-C modes, respectively.

To clarify that the interaction between the fast and slow modes mentioned above occurs and that the slow modes are destabilized, we have carried out the linear analysis of the electrostatic two-stream instability for a C_2H_3Cl plasma by artificially removing some ion species. Figure 5 shows the imaginary and real parts of instability frequency for $n_e = 0$ and $T_i = 2 \times 10^{-5}$ MeV, which are the same parameters as Fig. 4, but now by neglecting one of the ion species. Note that in all the cases, only two unstable modes are excited.

When reflected protons are removed ($n_{P-ref} = 0$) [Figs. 5(a)–5(d)], the unstable modes with γ_m at $k_m v_0 / \omega_{pe} \simeq 0.17$ (Exp-P mode) and 2.2 (Exp-C mode) remain and are identical to that with the reflected protons (Fig. 4), whereas the mode at $k_m v_0 / \omega_{pe} \simeq 0.085$ (Ref-P mode) disappears. This is because the slow Ref-P mode is removed and no interaction between the fast Exp-P mode occurs.

Next, when expanding protons are removed ($n_{P-exp} = 0$) [Figs. 5(e)–5(h)], whereas the unstable mode at $k_m v_0 / \omega_{pe} \simeq 2.2$ (Exp-C mode) remains and is identical to that with the expanding protons (Fig. 4), the unstable mode at $k_m v_0 / \omega_{pe} \simeq 0.17$ (Exp-P mode) disappears and the mode at $k_m v_0 / \omega_{pe} \simeq 0.085$ (Ref-P mode) down-shifts to $k_m v_0 / \omega_{pe} \simeq 0.06$. This is because the slow Exp-P mode is removed and no interaction between the fast Exp-C mode occurs. As a result, the Exp-P mode is not excited. Furthermore, since the fast Exp-P mode is removed, the slow Ref-P mode interacts with the fast Exp-C mode, and excite Ref-P mode at a down-shifted wavelength of $k_m v_0 / \omega_{pe} \simeq 0.06$.

Finally, when expanding C-ions are removed ($n_C = 0$) [Figs. 5(i)–5(l)], the unstable mode at $k_m v_0 / \omega_{pe} \simeq 0.085$ (Ref-P mode) is identical to that with the expanding-C-ions (Fig. 4), the mode at $k_m v_0 / \omega_{pe} \simeq 2.2$ (Exp-C mode) disappears and the mode at $k_m v_0 / \omega_{pe} \simeq 0.17$ (Exp-P mode) down-shifts to $k_m v_0 / \omega_{pe} \simeq 0.14$. This is because Exp-C mode is not excited, and since the slow Exp-P mode interacts with the fast Cl mode, Exp-P mode is excited at a down-shifted wavelength of $k_m v_0 / \omega_{pe} \simeq 0.14$.

From these results, we conclude that three unstable roots at $k_m v_0 / \omega_{pe} \simeq 0.085, 0.17$, and 2.2 for $n_e = 0$ and $T_i = 2 \times 10^{-5}$ MeV are unstable modes of Ref-P mode (reflected-

Panels (a), (b), (e), (f), (i), and (j) [(c), (d), (g), (h), (k), and (l)] are plotted for $kv_0/\omega_{pe} < 5$ [$kv_0/\omega_{pe} < 0.35$]. [(a), (b), (c), and (d)] $n_{P-ref} = 0$; [(e), (f), (g), and (h)] $n_{P-exp} = 0$; and [(i), (j), (k), and (l)] $n_C = 0$.

proton IBTI), Exp-P mode (heavy-ion IBTI), and Exp-C mode (heavy-ion IBTI), respectively, as shown in Fig. 4.

B. Cold ions with hot electrons: Excitation of the electron-ion acoustic instability (electron-ion AI) and the ion-ion acoustic instability (ion-ion AI)

Now we consider the effect of the electrons with $n_e = 7.0 \times 10^{20}$ cm^{-3} [$1/(k^2 \lambda_{De}^2) \neq 0$] and $T_e = 2$ MeV in addition to all four species of cold ions ($T_i = 2 \times 10^{-5}$ MeV). By adding electrons with Maxwellian velocity-distribution function to the cold drifting-ions, the system is possibly unstable to the electron-ion acoustic instability (electron-ion AI) as well as the ion-ion acoustic instability (ion-ion AI) [1,3–6,11,13,14,16], addition to the IBTI [1]. The electron-ion AI and ion-ion AI are excited in the electron background. Whereas the electron-ion AI is excited with the relative drift between electrons and ions, the ion-ion AI is excited when there is a relative drift between ion species. Therefore, in the multispecies ion plasma with relative drifts between ion species, both the electron-ion AI and ion-ion AI can be excited in addition to IBTI.

The instability condition for the ion-ion AI is expressed as $v_{ds}\cos\theta \leqslant 2c_s$, where v_{ds} is relative ion drift velocities among ion species, c_s is the ion-acoustic velocity, and θ is the angle between the propagation direction of the ion-ion AI and the x direction [4,5]. Therefore, when $v_{ds}/2c_s \leqslant 1$, $\theta = 0$ and the ion-ion AI occurs for $k = k_x$ and $k_y = 0$, which applies to our PIC results.

When hot electrons are added, 10 solutions appear. Two new modes result from Langmuir waves, $\omega^2 = \omega_{pe}^2 + 3k^2 T_e/m_e$. These modes, which are obtained from Eq. (4), are high-frequency solutions compared with other eight solutions and are not discussed further other than to state that this is equivalent to approximating Eq. (1) as Eqs. (5) and (6).

Figure 6 shows the imaginary and real parts of instability frequency for $n_e = 7.0 \times 10^{20}$ cm^{-3} and $T_i = 2 \times 10^{-5}$ MeV. We use the relativistic plasma frequency $\omega_{pe} = \sqrt{n_e e^2/\epsilon_0 \gamma m_e}$, with a Lorentz factor of $\gamma = 3T_e/m_e c^2 = 12$. Note that three unstable roots appear at $k_m v_0/\omega_{pe} \simeq 0.12$ (Ref-P mode), 0.14 (Exp-P mode), and 2.2 (Exp-C mode). Compared to the $n_e = 0$ case shown in Fig. 4, the k_m value and amplitude of γ_m are identical for Exp-C mode. Furthermore, for Exp-P mode, k_m and γ_m are slightly smaller (by factors of 1.2 and 2.0, respectively) than the $n_e = 0$ case. However, for Ref-P mode, whereas k_m is slightly larger (by a factor of 1.4), γ_m is much smaller (by a factor of 17) than the $n_e = 0$ case. This large reduction in γ_m for Ref-P mode suggests that this mode is either the electron-ion AI or ion-ion AI. We explain the details below.

When hot electrons are added to the cold ion dispersion relation, the $1/(k^2 \lambda_{De}^2)$ term in Eq. (5) is important. The real part of the dispersion relation is identical to that derived from Eq. (7) when $k \to \infty$ or when $1/(k^2 \lambda_{De}^2) = 0$. However, when $k \to 0$, the fast and slow modes become Re $[\omega]/\omega_{pe} \to 0$ instead of being $\pm \omega_{ds}$. In our calculation, the Debye length is $\lambda_{De} = 4.0 \times 10^{-7}$ m/s and $k\lambda_{De} > 1$ is satisfied when $kv_0/\omega_{pe} > 0.19$. For Ref-P and Exp-P modes, γ_m occurs at $k_m v_0/\omega_{pe} \simeq 0.12$ and 0.14, respectively, and the electrons are

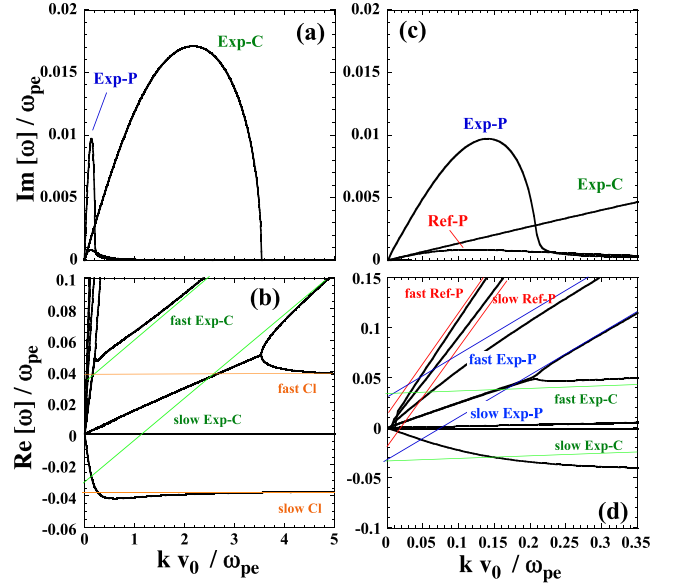

FIG. 6. Results of the linear analysis of the electrostatic two-stream instability for a C_2H_3Cl plasma when $n_e = 7.0 \times 10^{20}$ cm^{-3} and $T_i = 2 \times 10^{-5}$ MeV. [(a) and (c)] The imaginary part (Im $[\omega]/\omega_{pe}$) and [(b) and (d)] real part (Re $[\omega]/\omega_{pe}$) of the normalized frequencies versus normalized wave number in the x direction (kv_0/ω_{pe}. Panels (a) and (b) [(c) and (d)] are plotted for $kv_0/\omega_{pe} < 5$ [$kv_0/\omega_{pe} < 0.35$]. The thin red, blue, green, and orange lines in (b) and (d) are the fast and slow Ref-P, Exp-P, Exp-C, and Cl modes, respectively.

non-negligible. The real parts of the unstable modes shown in Figs. 6(b) and 6(d) reveal that, whereas γ_m for Exp-P mode occurs roughly at the interaction point of the fast Exp-C and the slow Exp-P modes, that for Ref-P mode occurs on the slow reflected-proton ion-acoustic mode [$\omega = kv_{dP-ref} - \sqrt{n_{P-ref}/n_e}\sqrt{k^2/(1 + k^2\lambda_{De}^2)}\sqrt{T_e/m_p}$] [see Eq. (6)].

These results indicate that Ref-P mode is either the electron-ion AI or ion-ion AI; whereas IBTI is dominant for Exp-P mode, small modification in the real and imaginary parts of the instability frequency appears due to the electron effect; and Exp-C mode is IBTI, since the condition for the excitation of IBTI $k_m \lambda_{De} \gg 1$ is satisfied. Further discussion is given below.

C. Finite-temperature ions

To extend the linear analysis to warm ions and hot electrons we solve Eq. (1) numerically with $T_i = 0.02$ MeV for all ion species, this includes the reflected protons, expanding protons, C^{6+} ions, and Cl^{15+} ions.

1. $T_i = 0.02$ MeV and $n_e = 0$: Ion Landau damping effect

Figure 7 shows the imaginary and real parts of the instabilities versus normalized wave number when $1/(k^2 \lambda_{De}^2) = 0$ or $n_e = 0$ and $T_i = 0.02$ MeV. Three unstable solutions, Ref-P, Exp-P, and Exp-C modes, appear. The k_m and γ_m result for Ref-P and Exp-P are similar to cold-ion case (Fig. 4) discussed
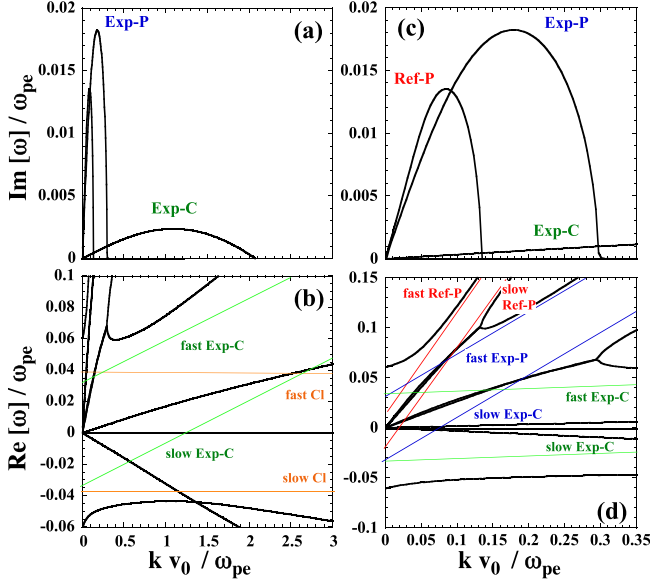

FIG. 7. Results of the linear analysis of the electrostatic two-stream instability for a C_2H_3Cl plasma when $n_e = 0$ and $T_i = 0.02$ MeV. [(a) and (c)] The imaginary part (Im $[\omega]/\omega_{pe}$) and (b), (d) real part (Re $[\omega]/\omega_{pe}$) of normalized frequency versus the normalized wave number in the x direction (kv_0/ω_{pe}). Panels (a) and (b) [(c) and (d)] are plotted for $kv_0/\omega_{pe} < 3$ [$kv_0/\omega_{pe} < 0.35$]. The thin red, blue, green, and orange lines in (b) and (d) are the fast and slow Ref-P, Exp-P, Exp-C, and Cl modes, respectively.

FIG. 8. Results of the linear analysis of the electrostatic two-stream instability for a C_2H_3Cl plasma when $n_e = 7.0 \times 10^{20}$ cm^{-3} and $T_i = 0.02$ MeV. [(a) and (c)] The imaginary part (Im $[\omega]/\omega_{pe}$) and [(b) and (d)] real part (Re $[\omega]/\omega_{pe}$) of normalized frequency versus the normalized wave number in the x direction (kv_0/ω_{pe}). Panels (a) and (b) [(c) and (d)] are plotted for $kv_0/\omega_{pe} < 3$ [$kv_0/\omega_{pe} < 0.35$]. The thin red, blue, green, and orange lines in (b) and (d) are the fast and slow Ref-P, Exp-P, Exp-C, and Cl modes, respectively.

in Sec. III A. However, for Exp-C mode, γ_m is a factor of 7.2 smaller and $k_m v_0/\omega_{pe}$ is downshifted by a factor of 2.0.

The reduction in γ_m and k_m in Exp-C mode results from the ion Landau damping. When $T_i = 2 \times 10^{-5}$ MeV as shown in Fig. 4, the γ_m appears at the real part of ω (ω_m) and k_m below the resonance condition between the slow Exp-C mode ($\omega = kv_{dC} - \omega_{pC}$) and the fast Cl mode ($\omega = \omega_{pCl}$), that is, $\omega_m < \omega_{pCl}$ and $k_m < (\omega_{pC} + \omega_{pCl})/v_{dC}$. When $T_i = 0.02$ MeV, i.e., $T_i > 0$ as shown in Fig. 7, the larger-k part of the instability is stabilized by the ion Landau damping in the region where $k\lambda_{DC} \geqslant 1$ is satisfied [1]. Here, λ_{DC} is the ion Debye length for C^{6+} ions. For $T_i = 0.02$ MeV, the condition of $k\lambda_{DC} = 1$ corresponds to $kv_0/\omega_{pe} = 2.9$. Since the smaller-k ($k < 1/\lambda_{DC}$) part of the instability is still unstable, both k_m and γ_m are reduced.

2. $T_i = 0.02$ MeV and $n_e = 7.0 \times 10^{20}$ cm^{-3}: Stabilization of the reflected-proton mode

Figure 8 shows the imaginary and real parts of the instability frequency versus normalized wave number, when $n_e = 7.0 \times 10^{20}$ cm^{-3} and $T_i = 0.02$ MeV. Note that only two unstable roots appear at $k_m v_0/\omega_{pe} \simeq 0.15$, Exp-P mode, and $k_m v_0/\omega_{pe} \simeq 1.1$, Exp-C mode, and Ref-P mode disappears. In comparison with cold-ion and hot-electron case (Fig. 6) discussed in Sec. III B, we find that whereas Exp-P mode is nearly identical, the maximum growth rate γ_m for Exp-C mode is reduced by a factor of 7.2 at a downshifted wavelength, $k_m v_0/\omega_{pe}$ by a factor of 2.0. These T_i effects are similar to the $n_e = 0$ case.
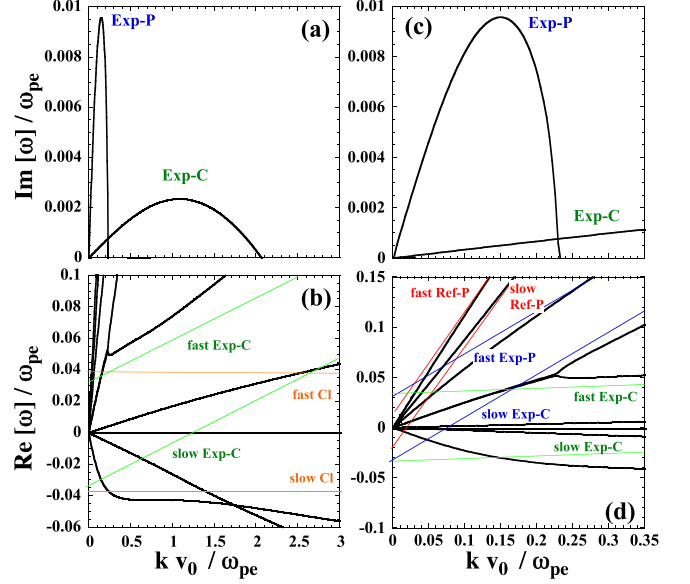

The reduction in γ_m occurs for Exp-C mode when $T_i = 0.02$ MeV even for the $n_e = 0$ case (Fig. 7). This implies the ion Landau damping is important. On the other hand, the stabilization of Ref-P mode is shown in Fig. 8 when $T_i = 0.02$ MeV and electrons are included. Again, this suggests that Ref-P mode is either electron-ion AI or ion-ion AI because the stability condition of the two instabilities is sensitive to the ion temperature.

D. Identification of the instabilities

Figure 9(a) shows the variation of the normalized growth rate versus the normalized wave number by changing T_i for $n_e = 0$. When $T_i = 2 \times 10^{-5}$ MeV [red marks in Fig. 9(a)], which is the same parameters as Fig. 4, three unstable modes, Ref-P, Exp-P, and Exp-C modes at $k_m v_0/\omega_{pe} \simeq 0.085$, 0.17, and 2.17, respectively, are seen. When $T_i = 0.01$ and 0.02 MeV, Ref-P, and Exp-P modes are similar, however, for Exp-C mode k_m and γ_m become smaller. This results from the ion Landau damping when $k\lambda_{Di} \geqslant 1$ is satisfied, which corresponds to $kv_0/\omega_{pe} \geqslant 4.0$ and 2.9, respectively, for $T_i = 0.01$ and 0.02 MeV. Therefore, the larger-k part of the unstable Exp-C mode is stabilized by the ion Landau damping when T_i is increased. Figure 9(b) displays the variation of the normalized growth rate versus the normalized wave number for 4 values of T_i and $n_e = 7.0 \times 10^{20}$ cm^{-3}.

Figure 5(b) in Paper I and Fig. 2(c) illustrate how the T_i are inferred from the PIC calculations of the velocity distributions. At 4 ps, these are ~ 0.3, ~ 0.1, and ~ 0.1 MeV for the expanding protons, C^{6+} and Cl^{15+} ions, respectively. In Fig. 9, results for $T_i = 0.4$ MeV are shown with black marks.
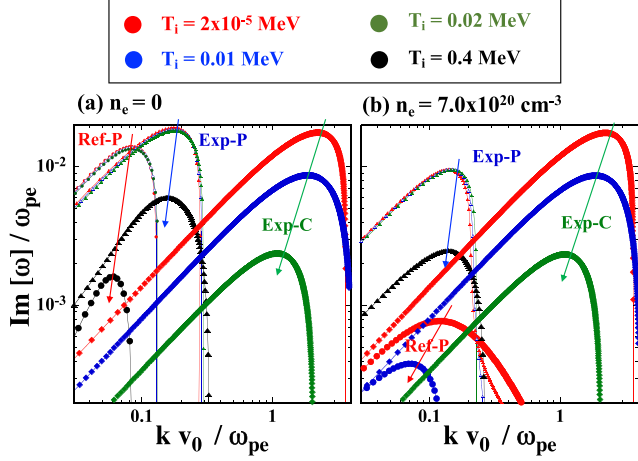

FIG. 9. Results of the linear analysis of the electrostatic two-stream instability for a C_2H_3Cl plasma including expanding C^{6+} ions, Cl^{15+} ions, protons, and reflected protons. The normalized growth rate (Im $[\omega]/\omega_{pe}$) versus the wave number in the x direction (kv_0/ω_{pe}). Ion temperature effect of the unstable modes for (a) $n_e = 0$ and (b) $n_e = 7.0 \times 10^{20}$ cm^{-3} for $T_i = 2 \times 10^{-5}$ MeV (red marks), $T_i = 0.01$ MeV (blue marks), $T_i = 0.02$ MeV (green marks), and $T_i = 0.4$ MeV (black marks). Ref-P mode (small-k roots, filled circles), Exp-P mode (medium-k roots, filled triangles), and Exp-C mode (large-k roots, filled diamonds) are shown. Arrows are guide to eyes.

A large reduction in γ_m for Ref-P and Exp-P modes when $n_e = 0$ [Fig. 9(a)] and for Exp-P mode when $n_e = 7.0 \times 10^{20}$ cm^{-3} [Fig. 9(b)] results from the ion Landau damping. Exp-C mode is also stabilized via the ion Landau damping from a lower temperature of $T_i \geqslant 0.03$ MeV and there are no unstable roots.

By comparing Figs. 9(a) and 9(b), we find the following effects of including hot electrons. (i) For Ref-P mode, the maximum growth rate γ_m is reduced more than an order of magnitude at slightly (by a factor of 1.4) up-shifted $k_m v_0/\omega_{pe}$. The upshift depends on T_i; this mode is stabilized ($\gamma_m/\omega_{pe} \simeq 6 \times 10^{-6}$) when $T_i = 0.02$ MeV as shown in Fig. 8. Ref-P mode is either the electron-ion AI or ion-ion AI. (ii) For Exp-P mode, γ_m is reduced by a factor of 2 when including hot electrons, and independent of T_i at $T_i < 0.1$ MeV. Exp-P mode is IBTI. (iii) For Exp-C mode, γ_m is independent of the hot electrons and strongly depends on T_i, so Exp-C mode is IBTI.

For Ref-P mode, the observed reduction of γ_m and upshift of k_m, which are observed by including hot-electrons, suggest that this mode is either the ion-ion AI or electron-ion AI. For the ion-ion AI, when the relative drift velocity between the different populations of ions is larger than the ion thermal velocity v_{thi}, $T_i = 0$ can be assumed. When $T_i = 0.02$ MeV, the relative drift velocity between the reflected and expanding protons ($v_{P-ref} - v_{P-exp} = 6.4 \times 10^{-2}c$) is larger than the thermal velocity of protons ($v_{thP} = 6.5 \times 10^{-3}c$). This implies that T_i effects are negligible for Ref-P mode so that this is not likely to be the ion-ion AI. In contrast, the growth rate of the electron-ion AI has T_i dependence as a result of the ion Landau damping [34]. Therefore, we conclude that Ref-P mode is the electron-ion AI.

FIG. 10. The temporal evolution of (a) the peak amplitude of the electrostatic fluctuation $E_{x,k}$ and (b) the dominant k_x in the PIC from the power spectrum of E_x taken at the width of $\Delta x = 10$ μm in a few μm upstream region of a shock in a C_2H_3Cl plasma. Solid and dotted lines in (a) represent growth rates of E_x, $\gamma = 1.0 \times 10^{12}$ s^{-1} and 2.4×10^{11} s^{-1}, derived from the exponential fits to the data at $t = 2.25$–2.75 ps and 2.75–4.0 ps, respectively.

IV. DISCUSSION

From the results shown in Sec. III, we conclude that the most unstable mode with the largest growth rate is Exp-P mode, which is IBTI with a small modification in both the real and imaginary parts of the frequency due to the hot electrons. Ref-P mode is the electron-ion AI ($k\lambda_{De} < 1$), whose growth rate strongly depends on T_i. Exp-C mode is IBTI ($k_m\lambda_{De} \gg 1$), which is stable because of the large ion Landau damping.

Now, we compare the results of the linear analysis with the PIC simulations. Figures 10(a) and 10(b) represent the temporal variation of the peak amplitude of the electrostatic fluctuation $E_{x,k}$ and the dominant k_x, respectively, obtained from the PIC simulations, where $E_{x,k} = (1/\sqrt{2\pi}) \int E_x(x) e^{-ik_x x} dx$ is the Fourier component of electric field. These values are derived from the power spectrum $E_{x,k}^2$ versus k_x, as shown in Figs. 4(d) and 4(e) of Paper I. We find that E_x shows the fast growth early in time at $t = 2.25$–2.75 ps and the slower growth later in time at $t = 2.75$–4.0 ps. The growth rate γ^{PIC} and the dominant k_x^{PIC} values at 4.0 ps are $\gamma^{PIC} = 2.4 \times 10^{11}$ s^{-1} and $k_x^{PIC} = 4.8$ μm^{-1}, respectively.

As described in Sec. III D, proton temperature T_P derived from the velocity spread obtained by PIC at 4 ps is $T_P \sim 0.3$ MeV. The maximum growth rate (γ_m^{Exp-P}) and the k_x value at the maximum growth rate (k_m^{Exp-P}) for the most unstable mode, Exp-P mode, derived from the linear analysis for $T_i = 0.4$ MeV shown in Fig. 9(b) are $\gamma_m^{Exp-P} = 1.1 \times 10^{12}$ s^{-1} ($\gamma_m^{Exp-P}/\omega_{pe} = 2.5 \times 10^{-3}$) and $k_m^{Exp-P} = 1.8$ μm^{-1} ($k_m^{Exp-P} v_0/\omega_{pe} = 0.14$), respectively. We find that k_m^{Exp-P} and k_x^{PIC} ($k_x^{PIC} v_0/\omega_{pe} = 0.37$) agree relatively well with each other, while γ_m^{Exp-P} is more than a factor of 4 larger than γ^{PIC} ($\gamma^{PIC}/\omega_{pe} = 5.6 \times 10^{-4}$).
FIG. 11. Proton temperature T_P dependence of (a) the normalized maximum growth rate ($\gamma_m^{\text{Exp-P}}/\omega_{pe}$) and (b) the normalized wave number in the x direction ($k_m^{\text{Exp-P}}v_0/\omega_{pe}$) of Exp-P mode obtained from the linear analysis for $n_e = 7.0 \times 10^{20}$ cm^{-3} at 4.0 ps. The drift velocity of the expanding protons $v_{\text{P-exp}}$ used in the linear analysis is $0.075c$ (filled circles) and $0.060c$ (open circles). The normalized growth rate ($\gamma^{\text{PIC}}/\omega_{pe}$) and the wave number in the x direction ($k_x^{\text{PIC}}v_0/\omega_{pe}$) obtained from the PIC simulation at 4.0 ps are 5.6×10^{-4} [horizontal solid line in (a)] and 0.37, respectively.

One of the possible explanations for $\gamma_m^{\text{Exp-P}} > \gamma^{\text{PIC}}$ is the difference in the proton temperature T_P. We inferred T_P from the velocity spread of the expanding protons from the PIC simulation, where the velocity distribution is far from a simple Maxwell distribution as shown in Fig. 2. Therefore, it is not easy to derive an accurate T_P. Figures 11(a) and 11(b) show the normalized maximum growth rate ($\gamma_m^{\text{Exp-P}}/\omega_{pe}$) and the normalized wave number in the x direction ($k_m^{\text{Exp-P}}v_0/\omega_{pe}$) of Exp-P mode, respectively, as a function of the proton temperature T_P for $n_e = 7.0 \times 10^{20}$ cm^{-3} at 4.0 ps. The drift velocity of the expanding protons $v_{\text{P-exp}}$ is $0.075c$ (filled circles) as shown in Table I. We see that to achieve the growth rate obtained by PIC at 4 ps, $\gamma^{\text{PIC}}/\omega_{pe} = 5.6 \times 10^{-4}$, $T_P \simeq 0.7$ MeV is required. This value is more than a factor of 2 larger than the T_P obtained by PIC calculations.

A second possible explanation for $\gamma_m^{\text{Exp-P}} > \gamma^{\text{PIC}}$ is the difference in the drift velocity of the protons $v_{\text{P-exp}}$. Table II summarizes drift velocities of expanding protons, C^{6+} and Cl^{15+} ions derived from the 2D PIC simulations at $t = 4.0$ ps for a C$_2$H$_3$Cl plasma. In our linear analysis, we used $v_{\text{P-exp}} = 0.075c$, which is the peak value of the expanding proton distribution function or the drift velocity of the high-velocity component v_P^H as shown in Fig. 2(c). In comparison, using a medium-velocity component $v_P^M = 0.06c$ for $v_{\text{P-exp}}$, there is reasonable agreement with theory. In Figs. 11(a) and 11(b), $\gamma_m^{\text{Exp-P}}/\omega_{pe}$ and $k_m^{\text{Exp-P}}v_0/\omega_{pe}$, respectively, for $v_P^H = 0.06c$ case are represented in open circles. We find that $\gamma^{\text{PIC}}/\omega_{pe} = 5.5 \times 10^{-4}$ agrees well with $\gamma_m^{\text{Exp-P}}/\omega_{pe} = 4.3 \times 10^{-4}$ at $T_P = 0.4$ MeV. In this case $k_x^{\text{PIC}}v_0/\omega_{pe} = 0.36$

TABLE II. Drift velocities of expanding protons, C^{6+} and Cl^{15+} ions derived from the 2D PIC simulations at $t = 4.0$ ps for a C$_2$H$_3$Cl plasma. The expanding velocities estimated from E_{TNSA} at 4 ps are also shown. These velocities are taken from Figs. 5 and 6 of Paper I.

agree within a factor of 3 with $k_m^{\text{Exp-P}}v_0/\omega_{pe} = 0.12$ at $T_P = 0.4$ MeV. These results indicate that Exp-P mode, which is an IBTI, is in the nonlinear regime at 4.0 ps. This nonlinearity occurs later in time and results in the saturation in the growth of the wave amplitude, the broadening of the proton velocity distribution, and the larger wave number compared with that for the resonant mode. We discuss this in the following.

We have also conducted the linear analysis using the plasma densities, drift velocities, and temperatures obtained from the PIC calculation at 2.5 ps. The temperatures of the expanding protons, C^{6+} and Cl^{15+} ions are ~0.07, ~0.07, and ~0.14 MeV, respectively. When $T_i = 0.07$ MeV, only Exp-P mode is excited and $\gamma_m^{\text{Exp-P}}/\omega_{pe} = 1.9 \times 10^{-3}$ and $k_m^{\text{Exp-P}}v_0/\omega_{pe} = 0.40$ are obtained. Compared with the growth rate and k_x values derived from the PIC at 2.5 ps (shown in Fig. 10), $\gamma^{\text{PIC}}/\omega_{pe} = 1.5 \times 10^{-3}$ ($\gamma^{\text{PIC}} = 1.0 \times 10^{12}$ s^{-1}) and $k_x^{\text{PIC}}v_0/\omega_{pe} = 0.51$ ($k_x^{\text{PIC}} = 12$ μm^{-1}), those from the linear analysis agree well within a factor of 1.3.

A better agreement between the results from the PIC and linear analysis is achieved when the plasma parameters at 2.5 ps are used compared with those at 4.0 ps. This might result from the fact that the velocity distribution of the expanding protons shown in Fig. 2 is close to a Maxwellian distribution at early time, similar to the distributions assumed by theory. In other words, at 2.5 ps Exp-P mode or IBTI is in the linear regime, and by 4.0 ps this instability has entered a nonlinear regime. Therefore, Exp-P mode is clearly observed in the PIC at 2.5 ps as the linear analysis predicts.

In Table II, the expanding velocities estimated from E_{TNSA} at 4 ps are also shown. These velocities are taken from Figs. 5 and 6 of Paper I. We find that, $v_C^L \simeq v_P^{\text{TNSA}} = 0.034c$, $v_C^H \simeq v_P^L = 0.042c$, $v_P^M = 0.90 \ v_P^{\text{TNSA}} = 0.060c$, and $v_P^H = 1.1 \ v_P^{\text{TNSA}} = 0.075c$. These results suggest that Exp-P mode, which is IBTI between expanding protons and C^{6+} ions, heats C^{6+} ions and generates the high-velocity component of v_C^H; at the same time, heats protons, generates the low-velocity component of v_P^L, and down-shifts v_P^M from v_P^{TNSA}. The velocity spectrum of C^{6+} ions at 2.0 and 4.0 ps is shown in Fig. 5 of Paper I, and the temporal variation of the low- and high-

velocity components of C^{6+} ions, v_C^L and v_C^H respectively, is shown in Fig. 6 of Paper I.

Possible explanations for the up-shift of v_P^H from v_P^{TNSA} are either by Exp-P mode or Ref-P mode. Ref-P mode, which is the electron-ion AI between electrons and reflected protons, can up-shift expanding protons and down-shift reflected protons. However, since the calculated γ_m for Ref-P mode is more than an order of magnitude smaller than that of Exp-P mode, the contribution of Ref-P mode should be negligible. Therefore, we conclude the up-shift of v_P^H from v_P^{TNSA} also results from Exp-P mode. Furthermore, $v_{Cl} = v_{Cl}^{TNSA} = 0.030c$ and no heating occurs for Cl^{15+} ions. This is consistent with the stabilization of Exp-C mode, which is BTI but a finite ion temperature causes the ion Landau damping.

To enhance the number of reflected and accelerated ions in a collisionless shock, it is important to have a large number of expanding ions with velocities above v_L^i. Excitation of electrostatic two-stream instabilities is a possible solution to increase the number of the reflected ions since ions are heated by them. In a multicomponent C_2H_3Cl plasma, excitation of the electrostatic two-stream instability between expanding protons and C^{6+} ions, which is Exp-P mode, results in heating of expanding protons and C^{6+} ions, and the number of the expanding ions with velocities above v_L^i increases. Furthermore, excitation of the electrostatic two-stream instability between expanding and reflected protons, which is Ref-P mode, results in heating of the expanding and reflected protons. The heating of expanding protons increases the number of the expanding protons with velocities above v_L^i, and results in a larger number of reflected protons. As a consequence, Ref-P mode is enhanced, and the energy spread of the reflected protons increases. Therefore, exciting Exp-P mode, while stabilizing Ref-P mode, is an ideal condition for generating a large number of quasimonoenergetic ions. In this study, we have highlighted that a large growth rate of Ref-P mode occurs when electrons are neglected, but a more realistic treatment including hot electrons suppresses this growth by more than an order of magnitude. This results from the suppression of IBTI and the excitation of the low growth-rate electron-ion AI for Ref-P mode. Furthermore, by using a multicomponent C_2H_3Cl plasma, IBTI between expanding protons and C^{6+} ions is excited, and the temperature of the expanding protons increases. This results in the ion Landau damping and further stabilization of Ref-P mode.

V. SUMMARY

In summary, 2D PIC simulations are used to study the formation of the laser-driven electrostatic collisionless shock in a multicomponent C_2H_3Cl plasma. The upstream expanding ion populations are accelerated by the nonoscillating electric field, which accelerates the heavier and lighter ions to different velocities. Furthermore, part of the ion populations in the upstream region is reflected and accelerated at the shock. These relative drifts between two ion populations result in the excitation of an electrostatic two-stream instability, which leads to the broadening of the upstream expanding-proton distribution.

A linear analysis of the instabilities for a C_2H_3Cl plasma is carried out using the one-dimensional electrostatic plasma

dispersion function for unmagnetized collisionless plasmas to identify the instability. The most unstable mode is the expanding-proton mode, which is the electrostatic ion-beam two-stream instability excited between the expanding protons and C ions. The reflected-proton mode, which is the electrostatic electron-ion acoustic instability excited between the reflected protons and electrons, is also unstable with the smaller growth rate compared with the expanding-proton mode, and the growth rate depends on the ion temperature. The expanding-C-ion mode, which is the electrostatic ion-beam two-stream instability excited between the expanding C and Cl ions, is stable results from the large ion Landau damping.

In a multicomponent, near critical-density plasma, the fast-growing electrostatic ion-beam two-stream instability is excited. This increases the number of reflecting and accelerating ions at an electrostatic collisionless shock, leading to brighter quasimonoenergetic ion beams.

APPENDIX: TEMPORAL EVOLUTION OF THE ELECTRON TERMPERATURE AND A DC ELECTRIC FIELD

The interaction of high-intensity laser with a relativistic near critical-density plasma results in uniform electron heating via $\vec{J} \times \vec{B}$ mechanism [35]. Figure 12(a) shows the electron phase space in a C_2H_3Cl plasma at $t = 4.0$ ps, where the vertical axis shows the four velocity $\gamma v/c$ (γ is the Lorentz factor) in the x direction. Figure 12(b) represents the electron energy spectrum taken at $\Delta x = 20$ μm in the upstream region just ahead of the shock front, this is shown by a vertical box in Fig. 12(a). To estimate the electron temperature (T_e) a 2D-relativistic Maxwellian $f(E) \propto E \exp(-E/T_e)$ is used to fit the electron energy spectrum as shown in Fig. 12(b). The extracted electron temperature is $T_e \simeq 2.0$ MeV. The temporal evolution of T_e is represented in Fig. 12(c). Early in time, at $t = 1.0$ ps, T_e is nearly equal to the initial temperature of 500 eV. After the interaction of the laser peak at $t = 1.0$ ps, T_e rises sharply and reached $\simeq 2.0$ MeV at $t = 2.50$ ps and remain the same throughout the simulations. The time evolution of T_e is very well fitted with a Sigmoid function, $S(t) = 1/(1 + e^{-at})$, where a is a fitting constant, and the derivative of this function peaks at $t = 1.75$ ps as shown in Fig. 12(c).

The ions in the upstream expanding plasma are accelerated by a uniform sheath electric field E_{TNSA}. Figure 13(a) shows the temporal evolution of E_{TNSA} measured from the PIC simulation (open circles). E_{TNSA} peaks at $t \simeq 2.5$ ps.
FIG. 12. (a) The electron phase space $\gamma v/c$ versus x, in a C_2H_3Cl plasma at $t = 4.0$ ps. The color scale shows the number of electrons in a log scale. (b) The electron energy spectrum taken at $\Delta x = 20$ μm in the upstream region of the shock front in a C_2H_3Cl (circles) plasma at $t = 4.0$ ps. The electron energy spectrum is fitted with a 2D-relativistic Maxwellian $f(E) = aE\exp(-E/T_e)$ (solid line), where a is constant, E is the energy of electrons, T_e gives the electron temperature in the upstream region. (c) The temporal evolution of T_e (open triangles) calculated by fitting a 2D-relativistic Maxwellian at each time. The T_e is very well fitted with a sigmoid function, $S(t) = 1/(1 + e^{-at})$ (blue solid line), and the derivative (dT_e/dt) of $S(t)$ (dot-dashed line), which peaks at $t = 1.75$ ps. Here a is a fitting constant. Normalized temporal evolution of the laser intensity (black solid line), which peaks at $t = 1.5$ ps, is also shown as a reference.

To qualify E_{TNSA} obtained from PIC, we estimate it by the temporal evolution of the expanding ion velocity in the upstream region. Figure 13(b) presents the velocity of Cl^{15+} ions (v_{Cl}, open triangles) taken at $\Delta x = 3$ μm in the upstream region of a C_2H_3Cl plasma. The temporal variation of v_{Cl} at

FIG. 13. (a) The temporal evolution of E_{TNSA} measured from the PIC (open circles, red line is guide to eyes) and derived from the v_{Cl} (blue lines) shown in (b). (b) The velocity of Cl^{15+} ions v_{Cl} (open triangles) derived from the peak of velocity spectrum dN/dv_{Cl} taken at $\Delta x = 3$ μm in the upstream region. The v_{Cl} is fitted to the 2nd order polynomial from $t = 1.0$ to 2.75 ps (green line), and a logarithmic curve from $t = 2.25$ to 4.0 ps (blue line). In (a), E_{TNSA} derived from the v_{Cl} follows a $\propto t$ from $t = 1.0$ to 2.75 ps (blue dotted line) and a $1/t$ dependences from $t = 2.25$ to 4.0 ps (blue solid line). Note that the x axis is in the log scale.

$t = 1.0$–2.75 ps shows a t^2 dependence on time, and a 2nd order polynomial is used to fit the v_{Cl} as shown in Fig. 13(b). Later in time, $t = 2.25$–4.0 ps, the v_{Cl} follows logarithmic dependence on time, and we use it to fit v_{Cl}. E_{TNSA} can be estimated by equating the electrostatic forces (ZeE_{TNSA}) with the acceleration ($Am_p dv/dt$) in the upstream region, where Z is the charge state, A is the mass number of the ion, m_p is the mass of the proton, e is the electron charge, and dv/dt is the acceleration. Therefore, E_{TNSA} is expressed as $E_{TNSA} = (A/Z)(m_p/e)(dv/dt)$. A derivative of the fitted v_{Cl} with $Z/A = 0.429$ for Cl ions shows that the $E_{TNSA} \propto t$ at $t = 1.0$–2.75 ps and a $1/t$ dependence at $t = 2.25$–4.0 ps as shown in Fig. 13(a). E_{TNSA} obtained from the PIC simulations and estimated from v_{Cl} show the same trend and agree relatively well with each other. Therefore, it is verified that Cl^{15+} ions are accelerated by E_{TNSA}. The logarithmic dependence of v_{Cl} and $1/t$ dependence of E_{TNSA} are predicted by Mora [36]. This temporally changing E_{TNSA} field accelerates the upstream ions to a uniform velocity over time.
