(Received 2 July 2014; published 20 March 2015)

When repelling particles are confined by a transverse potential in quasi-one-dimensional geometry, the straight line equilibrium configuration becomes unstable at small confinement, in favor of a staggered row that may be inhomogeneous or homogeneous. This conformational phase transition is a pitchfork bifurcation called the zigzag transition. We study the zigzag transition in infinite and periodic finite systems with short-range interactions. We provide numerical evidence that in this case the bifurcation is subcritical since it exhibits phase coexistence and hysteretic behavior. The physical mechanism responsible for the change in the bifurcation character is the nonlinear coupling between the transverse soft mode at the transition and the longitudinal Goldstone mode linked to the translational or rotational invariance of the zigzag pattern. An asymptotic analysis, near the bifurcation threshold and assuming an infinite system, gives an explicit expression for the normal form of the bifurcation. We establish the subcriticality, and we describe with excellent precision the inhomogeneous zigzag patterns observed in the simulations. A direct test of the physical mechanism responsible for the bifurcation character evidences a quantitative agreement.

I. INTRODUCTION

The zigzag transition is a configurational phase transition that happens when repelling particles in a plane are confined in quasi-one-dimensional (quasi-1D) linear traps by a transverse potential. When the transverse confinement potential is much greater than the interparticle energy, all particles are aligned along the trap axis at equilibrium. Below a critical transverse confinement, the equilibrium pattern undergoes a transition from a straight line toward a staggered row (homogeneous or inhomogeneous), which is called "zigzag."

The zigzag transition is easily described if one assumes a perfect zigzag pattern. Let us consider identical point particles of mass m located in the plane (xOy), transversally confined in a quasi-1D geometry by a harmonic potential of stiffness β , and interacting with a repulsive potential $U(r)$. Here Ox is the longitudinal axis of the cell and Oy is the transverse axis. In an infinite system (or with periodic boundary conditions in the longitudinal direction and an even number of particles), the zigzag pattern corresponds to particles located at points A_i of coordinates $\{2id, -h\}$ and at points B_i of coordinates $\{(2i + 1)d, +h\}$, where the zigzag height h is a constant (see Fig. 1).

The potential energy of any particle in Fig. 1, up to second-neighbor interactions, is

$$\begin{aligned}
 E &= U[\sqrt{d^2 + 4h^2}] + U(2d) + \frac{\beta}{2}h^2 \\
 &\approx U(d) + U(2d) + h^2 \left[\frac{\beta}{2} + \frac{2U'(d)}{d} \right] \\
 &\quad + \frac{2h^4}{d^3} [dU''(d) - U'(d)], \tag{1}
 \end{aligned}$$

where the rightmost member results from an expansion in h up to h^4 . This energy is invariant toward the axial symmetry $y \rightarrow -y$. When we decrease β , the minimum of energy at $h = 0$ becomes a local maximum, with two symmetric minima $\pm h$ with $h > 0$. The conformational transition takes place at a critical value $\beta_{ZZ} = -4U'(d)/d$. The energy landscape is

shown in Fig. 2 for $\beta < \beta_{ZZ}$. It exhibits the characteristic features of a *supercritical* pitchfork bifurcation.

The zigzag transition has been observed with ions in Paul's trap [1–7], with plasma dusts [8–12], with colloids [13], and with millimetric charged beads [14–16]. A supercritical bifurcation has been observed in simulations of periodic systems with Coulomb interaction [17–20] and also in some periodic systems with short-range interactions [14,21]. Most experiments have been done in linear traps of finite length, with repulsive boundary conditions at the edges. In these traps, the particles are not equidistant, and the simple expression (1) is not strictly valid. The equilibrium pattern is spindle-shaped, with the maximum zigzag height in the trap center. Nevertheless, one may expect the same phenomenology, with the uniform zigzag height h replaced by the maximum height. In these finite systems, the bifurcation is always found to be supercritical, for Coulomb systems [3,4,7,18] as well as for systems with short-range interactions [11,13–15,22].

In contrast, other experimental evidence contradicts the supercritical character of the bifurcation in periodic systems with short-range interactions. With plasma dust confined in an annulus, Sheridan [10] has observed a *stable* localized zigzag pattern, surrounded by aligned particles. We have also reported observations of inhomogeneous patterns and demonstrated that, for short-range interactions, the zigzag pattern in a periodic system is linearly unstable [16]. A subcritical bifurcation diagram has also been exhibited in the experiments of Straube *et al.* [13].

We can infer from the known literature that the character of the zigzag bifurcation in periodic systems is not necessarily the same as in finite systems with repulsive boundary conditions at the edges. This phenomenon has already been observed in the framework of instabilities, such as convection rolls [23–26], surface waves [27], or solidification fronts [28–30] in extended or annular geometries. In all of these systems, a supercritical pitchfork bifurcation was expected, while experiments in extended periodic cells exhibited a subcritical behavior. Because of the translational or rotational invariance of the system, the nonlinearities induce a coupling between the soft

FIG. 1. (Color online) A schematic illustration of the zigzag pattern. The solid lines indicate the interactions that are taken into account in the theoretical description.

mode due to the instability and the Goldstone mode due to the continuous symmetry breaking and therefore the subcriticality of the bifurcation [31–33].

In Ref. [32], the terms of the normal form of the bifurcation are deduced from symmetry arguments, but with numerical coefficients that are not explicitly given by the analysis. In our approach, the underlying microscopic dynamics of the zigzag transition is known from first principles, and the normal form is obtained in a constructive way. The normal form fulfills all the required symmetry properties, and it exhibits the subcritical character of the bifurcation. Moreover, explicit expressions are given for all coefficients of the normal form, which allow a quantitative comparison between the observed inhomogeneous zigzag patterns and the calculations based on the normal form. The coupling between the soft mode at the bifurcation and the phase mode due to the breaking of a continuous symmetry induces a shift of the longitudinal interparticle distance. We are able to test quantitatively this effect, and we find an excellent agreement with our simulations, validating with great precision the mechanism that traces back to the coupling between the two soft modes.

This paper is organized as follows: Section II reports on numerical simulations and provides evidence of a subcritical zigzag transition in periodic systems with short-range interactions. In Sec. III, we construct perturbatively the normal form near the bifurcation in the thermodynamic limit. We identify the range in the bifurcation parameter for which inhomogeneous zigzag patterns exist, and we calculate the shapes of these patterns. In Sec. IV, we take into account the finite-size effects and compare quantitatively the inhomogeneous zigzag patterns observed in our simulations to the calculated patterns. A conclusion in Sec. V summarizes our findings, and four Appendixes are devoted to some technicalities.

II. EVIDENCE OF A SUBCRITICAL ZIGZAG BIFURCATION

A. Equilibrium configurations

To discuss the equilibrium configurations, it is convenient to introduce the distance to threshold ϵ as $\beta = \beta_{ZZ}(1 - \epsilon)$. In Fig. 3(a), we plot the maximum height h of the observed zigzag pattern as a function of ϵ and compare it to the height h^* that minimizes the interaction energy (1) and corresponds to the perfect zigzag. Three areas may be identified in this plot. Near the threshold $\epsilon = 0$, h is small, scales as $\epsilon^{1/2}$, and is accurately given by the energy minimization [see Fig. 3(b)]. Increasing ϵ , the equilibrium pattern becomes inhomogeneous, as shown by the insets of Fig. 3(a), and the maximum zigzag height is larger than for a perfect zigzag pattern: $h > h^*$. Then when ϵ is further increased, a high height zigzag pattern is recovered, of height h^* . The extension of the interval of ϵ values for which inhomogeneous patterns are observed increases with the system size (at constant density and interaction range).

B. Linear instability of the zigzag pattern

A linear stability analysis of the zigzag pattern has been done in Ref. [16]. In the zigzag lattice, the longitudinal and transverse vibrations both exhibit high-frequency optical branches and low-frequency acoustical branches. For finite range interactions, we have shown that, in an infinite system, there is a whole band of small wave numbers for which transverse acoustic vibrations have a pure imaginary frequency, ω_{AT} . The relevant parameters are the zigzag height h and the interaction range λ_0 , expressed in units of the mean interparticle distance d . For small enough λ_0/d and small enough wave number, we have exhibited a range in zigzag height $h_{C1} \leq h \leq h_{C2}$ for which the frequency ω_{AT} is pure imaginary. These limiting heights are shown in Ref. [16] to bound the area of existence of the inhomogeneous patterns (see the right plot of Fig. 3). The appearance of inhomogeneous patterns is thus linked to a long-wavelength instability, which explains why they are more easily observed in large systems.

The heights h_{C1} and h_{C2} depend on the wave number q , with $h_{C1} \propto q$ when $q \rightarrow 0$. In a finite periodic system, the minimum nonzero wave number q_{\min} scales as the inverse of the system size L , thus $h_{C1} \propto 1/L$. Near the transition, the zigzag height scales as $\epsilon^{1/2}$, where ϵ is the distance to threshold. There is therefore a range in ϵ that scales as $1/L^2$ for which the bifurcation is supercritical. This explains the supercritical behavior evidenced by Fig. 3(b) and our previous results in Ref. [14].

C. Hysteretic behavior

In Fig. 4, we plot the maximum zigzag height h as a function of the ratio β/β_{ZZ} , for increasing and decreasing stiffnesses, and several system sizes. The density and interaction potential are kept constant. The evolution of the zigzag height clearly exhibits an hysteretic behavior. For decreasing confining transverse stiffness β , the bifurcation between a straight line $h = 0$ and a state with localized bifurcated patterns always happens at the same value, β_{down} . When β increases, the transition toward the state $h = 0$ takes place at a value

FIG. 3. (Color online) (a) Zigzag height h (mm) as a function of ϵ for 8 (thick red curve), 16 (thick green curve), and 32 (thick blue curve) particles. The fine solid black line indicates the expected height for a zigzag pattern h^* . For inhomogeneous zigzag, h is the maximum height of the pattern. In the insets, we show two typical inhomogeneous patterns. The dots are simulations data, while the lines are only guide to the eyes. (b) Onset of the zigzag transition zoomed near the bifurcation threshold for 32 particles. The solid line is the theoretical height h^* of a zigzag pattern, while the dots are simulations data.

$\beta_{\text{up}} > \beta_{\text{down}}$, and the greater the system size, the greater the difference $\beta_{\text{up}} - \beta_{\text{down}} > 0$.

In Fig. 5, we plot the evolution of $\beta_{\text{down}}/\beta_{ZZ}$ and $\beta_{\text{up}}/\beta_{ZZ}$ with the particles number N . This confirms that β_{down} is basically independent of N . In contrast, β_{up} increases and tends toward a limit value $\beta_{\text{up}}^{\infty}$ with $\beta_{\text{up}}^{\infty} - \beta_{\text{up}}^N \propto 1/N$. We have done these measurements at two temperatures. There is indeed no significant differences between the two sets of data, which ensures that we actually observe equilibrium patterns.

D. Discussion

Under the assumption of a perfect zigzag pattern, with equidistant particles alternately displaced from the bottom of the transverse potential well, the zigzag transition is found to be a supercritical pitchfork bifurcation. However, when an

even number of particles is placed in a periodic cell, the particle distribution at equilibrium may be inhomogeneous. Moreover, we have shown in [16] that the vibration modes of the zigzag pattern exhibit a band of unstable acoustic modes.

The observation of inhomogeneous patterns evidences the *coexistence* between bifurcated ($h \neq 0$) and nonbifurcated ($h = 0$) regions, which in the framework of Landau phase theory takes place for first-order phase transitions and not for second-order ones. Retranscribed in the language of bifurcations, this evidences a *subcritical* behavior of the pitchfork bifurcation for large systems. The subcritical character of the bifurcation is also evidenced by the hysteretic evolution of the maximum height of the equilibrium patterns when the transverse confinement is varied. The domain of stability of the inhomogeneous patterns (see Fig. 3) and the amplitude of the hysteresis cycles (see Figs. 4 and 5) depend on the

FIG. 4. (Color online) Evolution of the zigzag height h (mm) for increasing (orange points, see arrows) and decreasing (blue points, see arrows) β/β_{ZZ} . The relevant particle number N is indicated in the upper right corner of each plot. The mean interparticle distance d is the same in all plots.

FIG. 5. (Color online) Reduced stiffness β/β_{ZZ} at which a transition between aligned particles and localized zigzag happens as a function of the particle number N , at constant d . Blue dots are the measured values β_{down} for decreasing β . Orange dots and stars are the measured values β_{up} for increasing β . The thermodynamic temperature in the simulations (see Appendix A) is such that $U(d)/k_B T_b = 10^{-2}$ (dots) and $U(d)/k_B T_b = 10^{-4}$ (stars). The dashed line is the maximum height of the hysteresis calculated from the normal form [see Eq. (11)]. The inset is a log-log plot of the deviation to this maximum height as a function of N . The dotted line is of slope -1 .

system size, which implies that finite-size effects have to be taken into account.

The key ingredients for subcriticality, as will be shown in Sec. III, are the invariance of the system with a continuous symmetry, either translational or rotational, and the short range of the interactions. Using techniques developed to tackle instabilities in extended systems, we will describe the inhomogeneous equilibrium patterns that we observe.

III. SUBCRITICAL ZIGZAG TRANSITION IN THE THERMODYNAMIC LIMIT

Assuming the thermodynamic limit justifies a description of the system as a continuous medium described by partial

differential equations. According to our simulations results, the equilibrium patterns may be inhomogeneous, with a zigzag height that depends on the particle position. Therefore, a quantitative description of the inhomogeneous patterns, including nonlinear corrections, may be feasible with slowly varying space and time functions. This is done in this section, using theoretical tools developed for instabilities in extended systems [32].

A. Translational invariance and coupling with the phase mode

A zigzag pattern is invariant under translations $x \rightarrow (x + \phi)$, where ϕ is a real constant. Thus, in the long-wavelength and low-frequency limit, the energy required by a time- and space-dependent field $\phi(x, t)$ vanishes. Indeed, the field $\phi(x, t)$ is the Goldstone mode linked to the breaking of the translational invariance by the actual zigzag pattern. Very near the pitchfork bifurcation, there is also a soft mode linked to the bifurcation itself. It is a modulated zigzag pattern $h(x, t)$, slowly varying with space and time. In Ref. [32], it was shown that the normal form at the bifurcation results from the nonlinear coupling between these two soft modes.

In our calculations, we assume the vicinity of the zigzag transition, $|\epsilon| \ll 1$. This suggests that the zigzag height h scales as $\epsilon^{1/2}$. We therefore write $h = \epsilon^{1/2} H$, where H is of order 1. Then the slow time and space variables are chosen to recover the acoustic modes in the low-frequency and long-wavelength limit (see Appendix B). We thus take $T = \epsilon^{1/2} t$ and $X = \epsilon^{1/2} x$. The scale of the space variable defines the scale of the field $\phi = \epsilon^{1/2} \Phi$, where Φ is of order 1. The fields H and Φ depend on the slow variables X and T . As in Ref. [32], we will call $\Phi(X, T)$ the *phase field* [34].

As shown in Fig. 1, we consider only interactions up to second neighbors. It is the simplest model, since nearest-neighbor interactions only are insufficient to stabilize the zigzag pattern [16], while taking into account the second neighbors prohibits the zigzag collapse. With this assumption and our previous scaling choices, the relevant distances read

$$A_0 B_0 = \sqrt{[d + \epsilon^{1/2} \Phi(X + \epsilon^{1/2} d) - \epsilon^{1/2} \Phi(X)]^2 + \epsilon [H(X + \epsilon^{1/2} d) + H(X)]^2}, \quad (2)$$

$$A_0 A_1 = \sqrt{[2d + \epsilon^{1/2} \Phi(X + 2\epsilon^{1/2} d) - \epsilon^{1/2} \Phi(X)]^2 + \epsilon [H(X + 2\epsilon^{1/2} d) - H(X)]^2}. \quad (3)$$

Expanding the interaction energy $U(A_0 B_0) + U(A_0 A_1)$ up to ϵ^2 , and setting $\partial \Phi / \partial X \equiv \Phi_X$, we get

$$\begin{aligned} \tilde{E} \approx & U(d) + U(2d) + \epsilon H^2 \left(\frac{\beta}{2} + \frac{2U'(d)}{d} \right) + \epsilon^2 \left\{ \left[U''(d) - \frac{U'(d)}{d} \right] \left(\frac{2H^4}{d^2} + 2H^2 \Phi_X \right) \right. \\ & \left. + HH_{XX} d U'(d) + \Phi_X^2 \frac{d^2}{2} [U''(d) + 4U''(2d)] + H_X^2 \frac{d}{2} [U'(d) + 2U'(2d)] \right\}. \end{aligned} \quad (4)$$

The interaction energy \tilde{E} gives the Lagrangian density $\mathcal{L} = m\epsilon^2(\Phi_T^2 + H_T^2)/2 - \tilde{E}$. Notice that we have omitted a term proportional to Φ_X at order ϵ , and the two terms

$$\epsilon^{3/2} \left[2HH_X U'(d) + \frac{d^2}{2} (U'(d) + 4U'(2d)) \Phi_{XX} \right] = \epsilon^{3/2} \frac{\partial}{\partial X} \left[H^2 U'(d) + \frac{d^2}{2} (U'(d) + 4U'(2d)) \Phi_X \right] \quad (5)$$

and

$$\epsilon^2 \Phi_{XX} \frac{d^3}{6} (U'(d) + 8U'(2d)) = \epsilon^2 \frac{\partial}{\partial X} \left[\Phi_{XX} \frac{d^3}{6} (U'(d) + 8U'(2d)) \right], \quad (6)$$

because they all are exact X derivatives and thus do not contribute to the Lagrange equations [35]. The Lagrange equations for the fields $H(X, T)$ and $\Phi(X, T)$ are thus

$$m\epsilon^2 H_{TT} = -\epsilon \left(\beta + \frac{4U'(d)}{d} \right) H - \epsilon^2 \left[U''(d) - \frac{U'(d)}{d} \right] \left(\frac{8}{d^2} H^3 + 4H\Phi_X \right) - \epsilon^2 H_{XX} d [U'(d) - 2U'(2d)], \quad (7)$$

$$m\epsilon^2 \Phi_{TT} = \epsilon^2 d^2 [U''(d) + 4U''(2d)] \Phi_{XX} + 4\epsilon^2 \left[U''(d) - \frac{U'(d)}{d} \right] H H_X. \quad (8)$$

This system of equations exhibits the coupling between the soft zigzag mode $H(X, T)$ due to the vicinity of the pitchfork bifurcation [14,16] and the phase mode $\Phi(X, T)$ due to translational invariance, according to the mechanism described in Refs. [32,33]. It leads to the correct acoustic spectrum in the long-wavelength limit (see Appendix B), which justifies *a posteriori* the scaling choices for the slow scales X and T .

Note also that the terms in Eqs. (7) and (8) satisfy all symmetry requirements [27,32,33,36,37]. The translational invariance $x \rightarrow x + \Phi_0$ is preserved since only the X derivatives of Φ appear. The fact that all terms in (7) are odd in H while all terms in (8) are even in H reflects the invariance of the zigzag pattern under the transform $(H, \Phi) \rightarrow (-H, \Phi)$. It is easily checked that the equations are invariant under the X parity symmetry $(H, X, \Phi) \rightarrow (H, -X, -\Phi)$.

As a consistency check, we may also verify that these equations include the dependency of the transition threshold on the interparticle distance. We remark that Eq. (7) admits the special solution $\Phi_X = \Phi_X^0 = Cste$ and $H_X = 0$, which corresponds to a renormalization of the mean interparticle distance, which becomes $d_{\text{eff}} = d + \epsilon \Phi_X^0 d$. By considering the terms of (7) that are proportional to H , we see that their physical significance is indeed that the instability threshold has changed, to become

$$\begin{aligned} \beta_{ZZ}(d_{\text{eff}}) &= -\frac{4U'(d + \epsilon \Phi_X^0 d)}{d + \epsilon \Phi_X^0 d} \\ &= -\frac{4U'(d)}{d} - 4\epsilon \Phi_X^0 \left[U''(d) - \frac{U'(d)}{d} \right] + O(\epsilon^2). \end{aligned}$$

B. Subcritical normal form of the bifurcation

Most importantly, Eqs. (7) and (8) provide the nonlinear mechanism responsible for the change in the character of the bifurcation. Searching for a stationary solution $H_T = 0$, $\Phi_T = 0$, Eq. (8) is readily integrated to give

$$\Phi_X = -\frac{2[dU''(d) - U'(d)]}{d^3[U''(d) + 4U''(2d)]} H^2 \equiv -\alpha \frac{H^2}{d^2} \quad \text{with } \alpha > 0. \quad (9)$$

Injecting this expression in (7), and recalling $\beta + 4U'(d)/d = [4U'(d)/d]\epsilon$, we get that the height of a zigzag pattern

$H = Cste$ is given by

$$\underbrace{U'(d)}_{<0} \frac{H}{d} = -4 \underbrace{[dU''(d) - U'(d)]}_{>0} (2 - \alpha) \frac{H^3}{d^3} \equiv \frac{1}{4} g_3 \frac{H^3}{d^3}. \quad (10)$$

Without the coupling with the phase field Φ , $\alpha = 0$, and we recover the supercritical pitchfork bifurcation that can be deduced from (1). When the coupling is taken into account, the coefficient $(2 - \alpha)$ may change sign, so that the pitchfork bifurcation becomes subcritical. This happens when the interaction potential is of short range (see Appendix C). For the modified Bessel interaction used in our simulations, we have $(2 - \alpha) < 0$ when $d/\lambda_0 > 1.58$. Our simulations (see Sec. II) are done with $d/\lambda_0 \approx 3.92$. It is thus possible to observe a change in the character of the bifurcation because of the coupling with the phase field, and in Sec. IV we will show that this is indeed the case. In Appendix C, we also show that for the Coulomb potential $g_3 < 0$, which is consistent with the fact that the zigzag pattern is stable in a Coulomb system [16,17].

When $g_3 > 0$, the bifurcation is subcritical and it becomes necessary to calculate higher-order terms in Eq. (7) in order to get stable solutions above the bifurcation threshold and thus saturate the instability. We thus carry on the expansion of the energy (4) to higher-order terms. We find a $\epsilon^{5/2}$ term that is a total X derivative, and it may thus be dropped [38]. Then the ϵ^3 term is rather complicated. We keep only the terms in H^5 , $H^3\Phi_X$, and $H\Phi_X^2$. When gathered with the help of Eq. (9), they give a single term in H^5 . Higher derivatives of H happen, but for the sake of simplicity we neglect them. We will see in the next section that this crude approximation is numerically excellent.

We now turn back to the original variable h , and we use the interparticle distance d as the unit length. The normal form of the bifurcation is thus

$$mh_{TT} = \beta_{ZZ}\epsilon h + g_3 h^3 - g_5 h^5 + g_1 h_{XX}, \quad (11)$$

where the coefficient g_3 is defined in (10), and where

$$\begin{aligned} \beta_{ZZ} &\equiv -4U'(d) > 0, \\ g_1 &\equiv -[U'(d) - 2U'(2d)] > 0, \\ g_5 &\equiv 2\{2(6 - 6\alpha + \alpha^2)[U'(d) - dU''(d)] \\ &\quad + (2 - \alpha)^2 d^2 U'''(d)\} > 0. \end{aligned} \quad (12)$$

FIG. 6. (Color online) (a) In red (dark gray), we show the bifurcation diagram corresponding to (13). Solid (dotted) lines represent stable (unstable) solutions. In cyan (light gray), we sketch an hysteresis cycle. (b) : Homogeneous zigzag height h (for $h > 0$ only) as a function of the distance to threshold ϵ . Red solid line, stable solutions $h = 0$ and $h = h_+$. Red dotted line, unstable solution $h = h_-$ [see (13)]. Dashed black line, maximum height of bubbles solutions $h = h_{\text{bubble}}$ [see (18)]. The intersection of the lines h_{bubble} and h_+ corresponds to a wall solution and is emphasized by the large black dot.

The signs of the coefficients are valid for the conditions of our simulations (their respective numerical values are $\beta_{ZZ} = 115.8$, $g_1 = 28.2$, $g_3 = 208$, and $g_5 = 1489$). The coefficient g_3 is positive, so that the normal form (11) describes a *subcritical pitchfork bifurcation*. The sign of the coefficient g_5 ensures the stability of the bifurcated solution.

The homogeneous patterns are such that $h_X = 0$. With this assumption, the equilibria of (11) are readily found to be

$$h = 0, \quad \text{stable when } \epsilon < 0, \\ h_{\pm}^2 = \frac{1}{2g_5} (g_3 \pm \sqrt{g_3^2 + 4\epsilon\beta_{ZZ}g_5}). \quad (13)$$

The solutions $\pm h_-$ exist if $\epsilon_{\text{coex}} \equiv -g_3^2/(4\beta_{ZZ}g_5) \leq \epsilon \leq 0$, while the solutions $\pm h_+$ are defined for $\epsilon_{\text{coex}} \leq \epsilon$. The linear stability analysis is straightforward, and it shows that the solutions $\pm h_-$ are unstable whereas the solutions $\pm h_+$ are stable. The bifurcation diagram for the normal form (11) is that of a subcritical pitchfork bifurcation, as shown in Fig. 6. It allows for the coexistence between bifurcated and nonbifurcated solutions and the hysteresis cycles for $\epsilon_{\text{coex}} \leq \epsilon \leq 0$, in agreement with the simulation results of Sec. II.

C. Stationary inhomogeneous patterns

Here we search for stationary inhomogeneous patterns. The stationary solutions of Eq. (11) are such that $h_T = 0$ and are thus solutions of

$$g_1 h_{XX} = -\frac{dW}{dh} = -\frac{d}{dh} \left[\frac{1}{2}\epsilon\beta_{ZZ}h^2 + \frac{1}{4}g_3h^4 - \frac{1}{6}g_5h^6 \right]. \quad (14)$$

This equation is similar to the conservative equation of motion of a fictitious particle of mass g_1 in the potential $W(h)$, with the variable X playing the role of time [39].

For $\epsilon_{\text{coex}} \leq \epsilon \leq 0$, several inhomogeneous solutions $h_X \neq 0$ exist. They may be described with the help of the plots of $W(h)$ as a function of h , shown in Figs. 7, 8, and 9. For all values of ϵ , we have $W(0) = 0$, and under the assumption

$\epsilon_{\text{coex}} \leq \epsilon \leq 0$ this is a local maximum of $W(h)$ because the aligned particles ($h = 0$) are a stable homogeneous solution of (11). The unstable homogeneous solution h_- corresponds, in the mechanical analogy, to a local minimum of $W(h)$, and the stable homogeneous solution h_+ corresponds to a local maximum. An inhomogeneous pattern is defined, in the mechanical analogy, by its conserved “energy” W_0 .

1. Walls

The simplest inhomogeneous pattern to calculate is a *wall*, which links an homogeneous solution $h = 0$ to a bifurcated solution $h = h_+$, where h_+ is given by (13). A necessary condition for this coexistence is thus $W(h_+) = W(0) = 0$, which is only possible for a particular value ϵ_{wall} [see Fig. 6(b)], which is easily found to be

$$\epsilon_{\text{wall}} = -\frac{3}{16} \frac{g_3^2}{\beta_{ZZ}g_5}, \quad h_{\text{wall}} \equiv h_+(\epsilon_{\text{wall}}) = \sqrt{\frac{3g_3}{4g_5}}. \quad (15)$$

FIG. 7. (Color online) Plot of the dimensionless potential $W(h)$, Eq. (14), as a function of the dimensionless zigzag height h . We indicate the location h_- of the local minimum and the location h_+ of the local maximum. The plot is done for the particular value $\epsilon = \epsilon_{\text{wall}}$, such that $W(h_+) = W(0) = 0$.

FIG. 8. (Color online) Plot of the dimensionless potential $W(h)$ for $\epsilon_{\text{wall}} < \epsilon < 0$ [see Eq. (14)], as a function of the dimensionless zigzag height h . The line $W(h) = 0$ defines a bubble of height h_{bubble} .

Translating the mechanical analogy in the context of patterns, we see that $h \rightarrow 0$ for $X \rightarrow -\infty$ and $h \rightarrow h_{\text{wall}}$ for $X \rightarrow +\infty$, which justify calling this pattern a *wall*. Knowing two double roots of $W(h)$, we rewrite it in a particularly simple form,

$$W_{\text{wall}}(h) = -\frac{g_5}{6} h^2 (h_{\text{wall}}^2 - h^2)^2. \quad (16)$$

The function $W_{\text{wall}}(h)$ is plotted in Fig. 7. Equation (14) is then readily integrated to give the wall solution as

$$\frac{h(x)}{d} = h_{\text{wall}} \frac{\exp(\kappa x/d)}{\sqrt{1 + \exp(2\kappa x/d)}}, \quad \text{where } \kappa \equiv \frac{\sqrt{3}}{4} \frac{g_3}{\sqrt{g_1 g_5}}, \quad (17)$$

where we have restored the physical units, and we choose for the wall the position $x = 0$. A single wall cannot be observed in periodic systems because it obviously violates the periodicity condition.

2. Bubbles

When $\epsilon_{\text{wall}} < \epsilon < 0$, the maximum of $W(h)$ is strictly positive (see Fig. 8). Let us consider the “trajectory” that corresponds to the constant “energy” $W(0) = 0$. In this case,

FIG. 9. (Color online) Plot of the dimensionless potential $W(h)$ for $\epsilon_{\text{wall}} < \epsilon \leq 0$, Eq. (14), as a function of the dimensionless zigzag height h . The straight line of ordinate W_0 defines a nonlinear modulation between the minimum height h_1 and the maximum height h_2 .

the fictitious particle takes an infinite “time” to get away from the unstable equilibrium position $h = 0$, then a finite “time” to reach a maximum height h_{bubble} such that $W(h_{\text{bubble}}) = 0$, then an infinite “time” to come back to its initial position $h = 0$. In the framework of the zigzag transition, it corresponds to a localized zigzag of height h_{bubble} surrounded by aligned particles with $h(X \rightarrow \pm\infty) \rightarrow 0$. We call this pattern a *bubble*.

The bubble height h_{bubble} is the solution of $W(h_{\text{bubble}}) = 0$. The real nonzero roots of this equation are

$$h_{b_{\pm}}^2 = \frac{3}{2g_5} \left(\frac{g_3}{2} \pm \sqrt{\frac{g_3^2}{4} + \frac{4}{3}\epsilon g_5 \beta_{ZZ}} \right). \quad (18)$$

We have $h_{b-} \leq h_{b+}$, the equality corresponding to the case of a wall. The bubble height is thus $h_{\text{bubble}} = h_{b-}$, as shown in Fig. 8. In Fig. 6(b), we display the evolution of the bubble height with ϵ .

The potential $W(h)$ may be written

$$W_{\text{bubble}}(h) = \frac{g_5}{6} h^2 (h^2 - h_{b-}^2)(h_{b+}^2 - h^2). \quad (19)$$

A bit of algebra is sufficient to integrate (14) with this potential, giving

$$\frac{h(x)}{d} = \frac{h_{b-} - h_{b+}}{\sqrt{(h_{b+}^2 - h_{b-}^2) \cosh^2(\kappa' x/d) + h_{b-}^2}}, \quad (20)$$

where

$$\kappa' \equiv h_{b-} - h_{b+} \sqrt{\frac{g_5}{3g_1}} = \sqrt{\frac{-\epsilon \beta_{ZZ}}{g_1}}. \quad (21)$$

When $\epsilon \rightarrow \epsilon_{\text{wall}}$, it is easy to see that $\kappa' \rightarrow \kappa$, which means that the spatial variation of height for a bubble becomes equal to that for a wall. In this limit, the bubble height becomes independent of ϵ , but the bubbles are more and more flat [40]. An example is shown in the second plot of Fig. 10.

3. Modulated zigzag patterns

The minimum of $W(h)$ corresponds to the unstable homogeneous solution $\pm h_-$ [see Eq. (13)]. Let W_0 be a negative constant such that $0 > W_0 > W(\pm h_-)$. The equation $W(h) = W_0$ thus admits three real and positive solutions $h_1 < h_2 < h_3$, defined graphically in Fig. 9. In the mechanical analogy, it corresponds to a nonlinear periodic motion around $\pm h_-$, and it describes a *nonlinear modulation* of the zigzag pattern. Its minimum height is given by h_1 and its maximum height is given by h_2 .

In Appendix D, we show that the modulated patterns may be expressed in terms of Jacobi elliptic functions, as

$$\frac{h(x)}{d} = \frac{h_1 h_2}{\sqrt{h_2^2 \text{cn}^2\left(\frac{x - \Lambda K(Q)}{d\Lambda}, Q\right) + h_1^2 \text{sn}^2\left(\frac{x - \Lambda K(Q)}{d\Lambda}, Q\right)}}, \quad (22)$$

FIG. 10. (Color online) Comparison between simulations (blue points) and theoretical predictions (thick solid lines) for localized zigzag equilibrium patterns (bubbles). From top to bottom and left to right, $N = 32$ and $\epsilon_{\text{num}} = 0.07$, $N = 32$ and $\epsilon_{\text{num}} = 0.48$ [see the lower inset in Fig. 3 (a)], $N = 64$ and $\epsilon_{\text{num}} = 0.0264$, and $N = 64$ and $\epsilon_{\text{num}} = 0.261$. For clarity, the patterns maxima are placed at the center of the frame even if they can be anywhere in the periodic cell.

where $K(\cdot)$ is the complete elliptic integral of the first kind, and where

$$\Lambda \equiv \left[(h_3^2 - h_1^2) h_2^2 \frac{g_5}{3g_1} \right]^{-1/2}, \quad Q \equiv \frac{h_3 \sqrt{h_2^2 - h_1^2}}{h_2 \sqrt{h_3^2 - h_1^2}}. \quad (23)$$

The solution (22) is such that the maximum height takes place at $x = 0$, and $2\Lambda K(Q)$ is the wavelength of the spatial modulation. As explained in Appendix D, the modulated pattern is fully determined by the two parameters ϵ and h_2 , which is particularly well suited to our analysis.

IV. FINITE-SIZE EFFECTS

In the preceding section, we found a mechanism that explains why the zigzag transition actually is a subcritical bifurcation in translationally invariant infinite systems with short-range interactions. The key phenomenon is the nonlinear coupling between the soft mode at the zigzag transition and the phase mode linked to the translational invariance. This phenomenon also happens in *finite* systems with periodic boundary conditions because of their rotational invariance.

The subcritical bifurcation diagram of Fig. 6 is also relevant for periodic systems with short-range interactions. It is consistent with the observations reported on in Sec. II. The agreement is also quantitative. For instance, the hysteresis cycles displayed in Fig. 5 are consistent with a limiting value of the stiffness gap $\beta_{\text{up}} - \beta_{\text{down}}$ equal to $\epsilon_{\text{coex}}(d)\beta_{ZZ}(d)$ when $N \rightarrow \infty$.

In the simulations, the inhomogeneous patterns are observed when the stiffness β_{num} of the confining potential is such that $\beta_{\text{num}} < \beta_{ZZ}(d)$. This defines a *positive* parameter ϵ_{num} as $\beta_{\text{num}} = \beta_{ZZ}(d)(1 - \epsilon_{\text{num}})$. In contrast, the inhomogeneous patterns are predicted for *negative* values of ϵ . In this section, we will explain how to get rid of this apparent discrepancy by taking into account finite-size effects.

A. Localized zigzag patterns

Let us first focus on the bubbles. In these patterns, we can measure the distance between any two aligned particles. This distance d_{eff} is found to be constant, and such that $d_{\text{eff}} > d$ because the particles in the localized zigzag allow the others to expand. From this interparticle distance, we define an *effective* bifurcation parameter ϵ_{eff} ,

$$\epsilon_{\text{eff}} = 1 - \frac{\beta_{\text{num}}}{\beta_{ZZ}(d_{\text{eff}})}. \quad (24)$$

We will interpret a bubble observed in the finite periodic system as a bubble in an infinite system, with an interparticle distance d_{eff} , when the distance to threshold is ϵ_{eff} .

Notice that for consistency ϵ_{eff} must be *negative*, with $\epsilon_{\text{wall}}(d_{\text{eff}}) < \epsilon_{\text{eff}} \leq 0$, because it is a necessary condition for the existence of bubbles in infinite systems. This is indeed what happens, as shown by the data summarized in Table I. The effective bifurcation parameter becomes negative because $d_{\text{eff}} > d$ and the zigzag threshold $\beta_{ZZ}(d) = -4U'(d)/d$ is a strongly decreasing function of d . So, once the value of d_{eff} is measured on the simulation data, the bubble is completely

TABLE I. Summary of the effective distance to the threshold, ϵ_{eff} , and of the relative discrepancy $|L - \tilde{L}|/L$ corresponding to several localized excitations. The theoretical expectation \tilde{L} is given by Eq. (25) in all cases except the last one, which concerns two identical bubbles (see Fig. 10), thus requiring the change $\alpha \rightarrow 2\alpha$. For the sake of comparison, $d = 1.875$ mm.

N	d_{eff} (mm)	ϵ_{num}	ϵ_{eff}	$ L - \tilde{L} /L$ (%)	$(Nd_{\text{eff}} - L)/L$ (%)
16	1.967	0.206	-0.037	0.17	4.9
32	1.910	0.070	-0.0230	0.02	1.9
32	1.929	0.110	-0.042	0.09	2.9
32	2.120	0.480	-0.052	0.04	13.1
64	1.897	0.0284	-0.036	0.01	1.2
64	1.893	0.021	-0.032	0.05	1.0
64	1.996	0.261	-0.050	0.30	6.5

determined with the help of Eqs. (20) and (18), where all coefficients g_i , defined in Eqs. (10) and (12), are calculated for an infinite system in which the aligned particles are separated by d_{eff} .

This analysis is done on several simulations data, and the results are shown in Fig. 10. In each case, the effective distance d_{eff} is easily measured, and the comparison between the simulations and the bubbles expected from the theoretical analysis evidences an excellent agreement [41]. In the last plot of Fig. 10, the same value of d_{eff} is used for both bubbles, which have the same height. Equilibria with several bubbles are sometimes observed, and in all cases all bubbles have the same height, which is consistent with our analysis.

The comparison illustrated in Fig. 10 provides a quantitative test of the mechanism expressed by Eq. (9). The physical significance of the phase field Φ is a shift in the interparticle distance, which becomes $d_{\text{eff}}(1 + \Phi_X)$. Equation (9) relates the phase gradient Φ_X to the local zigzag amplitude. Physically, it expresses that the dilatation of the aligned particles is compensated by the height $h(X)$ of the bubble. This provides a second quantitative test of the coupling between the soft mode at the bifurcation and the Goldstone mode linked to rotational symmetry breaking that is at the basis of the calculations of Sec. III.

Indeed, the total length \tilde{L} occupied by a bubble is

$$\begin{aligned} \tilde{L} &= d_{\text{eff}} \left(N - \alpha \int_{-\infty}^{\infty} \frac{h(X)^2}{d_{\text{eff}}^2} dX \right) \\ &= d_{\text{eff}} \left[N - \frac{2\alpha h_{b-} h_{b+}}{\kappa'} \operatorname{arctanh} \left(\frac{h_{b-}}{h_{b+}} \right) \right]. \end{aligned} \quad (25)$$

For consistency, this length \tilde{L} has to be identical to the period L of our simulated cell. In Table I, we calculate $|L - \tilde{L}|/L$ for several bubbles, and we see that it is indeed very small. Since d_{eff} is rather close to d , we compare it to $(Nd_{\text{eff}} - L)/L$. We see that the calculated longitudinal width \tilde{L} is a much better estimate of the bubble width than the rough approximation Nd_{eff} . The last line of Table I corresponds to the two-bubble excitation of Fig. 10, so that we have consistently doubled the contribution of the integral in (25) in this last case.

B. Modulated zigzag patterns

We also observe modulated patterns, for which the zigzag height varies from a minimum $h_1 > 0$ to a maximum value

TABLE II. Summary of the effective distance to the threshold, ϵ_{eff} , and of the relative discrepancy $|L - \tilde{L}|/L$ corresponding to several modulated excitations. The theoretical expectation \tilde{L} is given by Eq. (26). For the sake of comparison, $d = 1.875$ mm.

N	d_{eff} (mm)	ϵ_{num}	ϵ_{eff}	h_2 (mm)	$ L - \tilde{L} /L$ (%)	$(Nd_{\text{eff}} - L)/L$ (%)
16	1.932	0.132	-0.0257	0.306	0.35	3.1
16	1.943	0.150	-0.0351	0.398	0.87	3.6
16	1.962	0.187	-0.0463	0.500	2.26	4.6
32	1.897	0.050	-0.0137	0.239	0.12	1.2
64	1.881	0.017	-0.0012	0.058	0.18	0.34
64	1.882	0.018	-0.0019	0.085	0.19	0.38
64	1.884	0.021	-0.0047	0.137	0.18	0.47

h_2 (see the upper inset in Fig. 3). For modulated patterns, it is impossible to measure directly the parameter d_{eff} , since no particles in the cell are along a straight line. In contrast, the height h_2 is easily measured from the simulation data. Then the unknown parameter d_{eff} is determined numerically from a consistency condition, requiring the spatial period of the modulation to be equal to the length L of the periodic box. The effective distance d_{eff} is thus the real root of the equation $L = 2\Lambda(h_2, d_{\text{eff}})K[Q(h_2, d_{\text{eff}})]$. With the help of (D2) and (24), this equation involves only the unknown parameter d_{eff} . This is a formally complicated equation that is easily solved numerically. Once d_{eff} and h_2 are known, the modulated pattern is completely determined. In Table II, we summarize the calculated values of d_{eff} and ϵ_{eff} , defined in Eq. (24). For consistency, the parameter ϵ_{eff} must be negative since modulated zigzag patterns happen only when the unstable homogeneous solution $\pm h_{\pm}$ exists. This is indeed the case for all patterns listed in Table II.

The comparison between the observed modulated patterns and the theoretical predictions of Eqs. (22) and (23) is done in Figs. 11 and 12. For the larger systems (32 and 64 particles), the agreement is excellent, and we are able to reproduce the strongly nonsinusoidal pattern in all cases. We display also in Fig. 12 the data for a small system of only 16 particles. Even in this rather unfavorable case, there is a very good agreement between the patterns calculated for an infinite system and the simulation results. It is of interest to emphasize that for the highest value $\epsilon_{\text{num}} = 0.206$ in Fig. 12, it is impossible to describe the pattern as a modulation, because there is no real solution to the numerical equation $L = 2\Lambda K(Q)$. It is nevertheless possible to describe it as a bubble, with a slightly different method from the one mentioned in Sec. IV A. We determine the parameter d_{eff} from the measurement of the pattern height, through Eq. (18).

The same consistency check of Eq. (9) as for bubbles may be done. The total length \tilde{L} of a modulated pattern, following the same reasoning that led to (25), is

$$\begin{aligned} \tilde{L} &= d_{\text{eff}} \left(N - 2\alpha \int_0^{L/2} \frac{h(X)^2}{d_{\text{eff}}^2} dX \right) \\ &= d_{\text{eff}} \left[N - 2\alpha h_1^2 \Pi \left(1 - \frac{h_1^2}{h_2^2}, Q \right) \right], \end{aligned} \quad (26)$$

FIG. 11. (Color online) Modulated zigzag patterns. From top to bottom and left to right: $N = 32$ and $\epsilon_{\text{num}} = 0.05$, and then $N = 64$ and $\epsilon_{\text{num}} = 0.0173, 0.0185$, and 0.0207 . Blue points denote simulation data, while the thick red solid line represents the theoretical prediction, Eq. (22).

where we have used the fact that the spatial period of a modulated pattern is L , the symmetry of the pattern, and where we have introduced the complete elliptic integral of the third kind $\Pi(\dots)$ [42]. The results are summa-

rized in Table II. We see that for these patterns also the error made on the estimated longitudinal width of the pattern is small, and much smaller than the rough estimate Nd_{eff} .

FIG. 12. (Color online) Modulated zigzag patterns for $N = 16$. From top to bottom and left to right: $\epsilon_{\text{num}} = 0.132, 0.150, 0.187$, and 0.206 . Blue points denote simulation data, while the thick red solid line represents the theoretical prediction, Eq. (22). The thick green solid line is the theoretical prediction (20), because this pattern cannot be described by a nonlinear modulation.

V. CONCLUSION

In this paper, we discuss the zigzag transition in systems of particles with short-range interactions, which are either infinite or with periodic boundary conditions in the longitudinal axis. With numerical simulations, we give evidence that the equilibrium patterns are not necessarily homogeneous. In sufficiently large systems, the zigzag transition is a first-order configurational transition. The relevant physical mechanism has been identified for instabilities in extended systems, and it results from the nonlinear coupling between the soft mode due to the zigzag transition and a Goldstone mode due to the breaking of the translational or rotational invariance of the system by the zigzag pattern.

In the framework of instabilities in extended systems, the subcritical normal form has been obtained phenomenologically by taking into account the symmetries of the system. In the case of the zigzag transition, the underlying dynamics is explicitly known. It allows us to obtain the normal form in a constructive way, as a systematic asymptotic expansion in the thermodynamic limit, near the bifurcation threshold. We provide analytical expressions of the normal form coefficients and establish the subcritical character of the pitchfork bifurcation.

At the end of the calculation, there is no free fitting parameter, and we are able to perform a quantitative comparison between our simulation data and the theoretical analysis. We describe with excellent precision the inhomogeneous zigzag patterns exhibited in the simulations. The physical significance of the coupling between the soft mode and the phase mode is a shift of the longitudinal interparticle distance, which depends on the local zigzag height. A direct and quantitative test of this mechanism is done and evidences a very good agreement.

ACKNOWLEDGMENTS

We thank S. Fauve for useful discussions, and for pointing out the relevance of the phase instability mechanism.

APPENDIX A: NUMERICS

The details on the numerical algorithm can be found in Ref. [43]. For the sake of completeness, we give a short summary below.

We simulate identical point particles located in the plane (xOy), submitted to a thermal bath at temperature T_b . The thermal bath is accounted for by a damping constant γ , and by random forces applied on each particle, with the statistical properties of uncorrelated white Gaussian noise. As for most of the experimental configurations for which the zigzag transition is relevant [3,5,7–11,13,18,44], the particles interact with a repulsive potential. We use in all simulations a screened electrostatic interaction $U(r) = U_0 K_0(r/\lambda_0)$ with energy scale U_0 , with a characteristic length λ_0 and

where K_0 is the modified Bessel function of index 0. To observe equilibrium patterns, the temperature of the thermal bath is such that $U(d)/(k_B T_b) < 0.01$ in all simulations.

The particles are transversally confined in a quasi-1D geometry by a harmonic potential of stiffness β , whereas periodic boundary conditions are applied in the longitudinal direction. The dynamics of the system is then simulated by the numerical integration of the coupled Langevin equations. Let L be the length of the simulation cell, and let N be the number of particles. In all simulations, the mean distance $d \equiv L/N$ is kept constant, with a length of $L = 60$ nm for $N = 32$. The influence of the potential range λ_0 has been discussed in [16]. We set $\lambda_0 \approx d/4$ in order to have a linearly unstable zigzag pattern. In some simulations, we vary the stiffness β by steps. The typical duration of a stiffness step is 10^4 time steps, and we make typically 10^3 stiffness steps (sometimes up to 10^5 steps) with a relative stiffness variation of 10^{-3} .

The simulations are done at finite (nonzero) temperature, hence the observed patterns are stable under the thermal fluctuations. To obtain the equilibrium patterns, we average the system motions on a time scale that is intermediate between the time step and the duration of a simulation run. Since this latter is never less than 10^6 time steps, the typical averaging time for an equilibrium pattern is 10^3 time steps.

APPENDIX B: ACOUSTIC MODES OF THE ZIGZAG PATTERN

In this appendix, we show that Eqs. (7) and (8) correctly describe the acoustic modes of the chain. We recover only the long-wavelength limit, because it is assumed at the beginning of the calculations of Sec. III A that X is a slow variable.

Taking $H = 0$, and linearizing (8), we get the sound velocity $c_s^2 = d^2[U''(d) + 4U''(2d)]/m$ of the rectilinear chain when nearest-neighbor and next-nearest-neighbor interactions are taken into account [43]. Taking $\Phi = Cste$, and linearizing (7) for $\beta = \beta_{ZZ}$, we recover the velocity of transverse oscillations $c_\perp^2 = d[2U'(2d) - U'(d)]/m$ as in Ref. [14].

In the general case, we linearize around the bifurcated homogeneous state H_0 , which from Eq. (1) is seen to be $H_0^2 = \beta_{ZZ} d^2 / (8[U''(d) - \frac{U'(d)}{d}])$. Assuming $H(X, T) = H_0 + \eta(X, T)$ with $|\eta| \ll 1$ and $|\Phi_X| \ll 1$, we obtain from (7) and (8)

$$\begin{aligned} m\eta_{TT} &= -2\beta_{ZZ}\eta - d[U'(d) - 2U'(2d)]\eta_{XX} \\ &\quad - 4 \left[U''(d) - \frac{U'(d)}{d} \right] H_0 \Phi_X, \\ m\Phi_{TT} &= d^2[U''(d) + 4U''(2d)]\Phi_{XX} \\ &\quad + 4 \left[U''(d) - \frac{U'(d)}{d} \right] H_0 \eta_X. \end{aligned} \quad (\text{B1})$$

Searching the solutions in the form $(\eta, \Phi) = (\eta_0, \Phi_0)e^{i(qX - \omega T)}$, we find the eigenfrequencies as the eigenvalues of the matrix,

$$\frac{1}{m} \begin{pmatrix} 2\beta_{ZZ} - d[U'(d) - 2U'(2d)]q^2 & 4iq[U''(d) - \frac{U'(d)}{d}]H_0 \\ -4iq[U''(d) - \frac{U'(d)}{d}]H_0 & d^2[U''(d) + 4U''(2d)]q^2 \end{pmatrix}. \quad (\text{B2})$$

FIG. 13. (Color online) Plot of $\alpha(u)$ (linear scale) as a function of u (log scale) for the modified Bessel function potential (blue curve) and the Yukawa potential (red curve).

This has to be compared with the calculations of Ref. [16], restricted to the second neighbors only, in the long-wavelength limit $\psi = qd \rightarrow 0$, and where all coefficients have to be expanded up to first order in h_0 only. The acoustic spectrum is then consistently recovered.

The scaling $h_0 = H_0\sqrt{\epsilon}$ is imposed by the pitchfork bifurcation, and we see that the acoustic modes are recovered if ω^2 , q^2 , and h_0^2 all are of order ϵ , which is ensured by the scalings of the slow variables $T = \epsilon^{1/2}t$, $X = \epsilon^{1/2}x$ as announced in the beginning of Sec. III A.

APPENDIX C: NUMERICAL ESTIMATES OF α

In this appendix, we discuss the numerical value of the parameter α defined in Eq. (9), which is directly linked to the subcritical or supercritical character of the bifurcation in infinite or periodic systems. Let us first consider short-range potentials, such as the modified Bessel function used in the simulations (see Appendix A) and the Yukawa potential. Let $u \equiv d/\lambda_0$. For the modified Bessel potential, we get

$$\alpha(u) = \frac{2u [K_0(u) + K_2(u)] + 4K_1(u)}{u\{K_0(u) + K_2(u) + 4[K_0(2u) + K_2(2u)]\}}. \quad (\text{C1})$$

Since $K_n(u) \sim e^{-u}/\sqrt{2\pi u}$ for large u , we easily see that $\lim_{u \rightarrow \infty} \alpha(u) = 2$. The function $\alpha(u)$ is plotted in Fig. 13. We find that $\alpha \geq 2$ for $d/\lambda_0 \geq 1.58$, and that the maximum value of α is 2.33.

For the Yukawa potential, we get

$$\alpha(u) = \frac{2(u^2 + 3u + 3)}{u^2 + 2u + 2 + e^{-u}(2u^2 + 2u + 1)}, \quad (\text{C2})$$

which also gives $\lim_{u \rightarrow \infty} \alpha(u) = 2$. The function $\alpha(u)$ is plotted in Fig. 13. We find that $\alpha \geq 2$ for $d/\lambda_0 \geq 0.61$, and that the maximum value of α is 2.32.

The numerical value of α for the modified Bessel potential explains an observation made in Ref. [16]. Here it was shown that if we consider a bubble pattern, the distance between nearest neighbors in and outside the bubble was almost constant. In our description, the particles outside the bubble are at a distance d_{eff} , while those inside the bubble are separated from $\sqrt{(d_{\text{eff}} - \alpha h^2)^2 + 4h^2}$. Since $(\alpha - 2)$ is positive but small, and since h/d is also small, the difference between these two distances is less than 1.5%.

It is of interest to consider also the case of the Coulomb potential. It is not difficult to extend our calculations to more than second-neighbor interactions. If we take into account the n th cell after the tagged one, one has to expand $A_0 B_n$ and $A_0 A_n$. This amounts to replacing d in Eq. (2) by $(2n + 1)d$, and $2d$ in Eq. (3) by $2nd$, and to sum on all interacting particles. The expansion in powers of ϵ is consistent if $n\epsilon \ll 1$, which excludes an infinite system. Let us therefore consider a finite periodic system of N_{max} cells. The coefficient g_3 is now found to be

$$\begin{aligned} \frac{g_3}{8} &= \frac{\left(\sum_{n=0}^{N_{\text{max}}} \frac{(2n+1)dU''[(2n+1)d] - U'[(2n+1)d]}{(2n+1)d}\right)^2}{\sum_{n=1}^{N_{\text{max}}} n^2 d^2 U''(nd)} \\ &\quad - \sum_{n=0}^{N_{\text{max}}} \frac{(2n+1)dU''[(2n+1)d] - U'[(2n+1)d]}{(2n+1)^3 d^3}. \end{aligned} \quad (\text{C3})$$

For the Coulomb potential, $U(r) \propto 1/r$, the sums in the numerators converge rapidly at large N_{max} while the sum in the denominator diverges. Hence $g_3 \leq 0$ (with the equality for $N_{\text{max}} = 1$) and the bifurcation is always supercritical, which is consistent with the linear stability analysis of zigzag patterns [16,17].

APPENDIX D: NONLINEAR MODULATED ZIGZAG

When $\epsilon_{\text{wall}} < \epsilon < 0$, the potential $W(h)$ has a minimum $W_{\text{min}} < 0$. Let W_0 be a constant such that $W_{\text{min}} < W_0 < 0$. Then the equation $W(h) = W_0$ has three real roots $h_1^2 < h_2^2 < h_3^2$, so that we may write

$$W_0 - W(h) = \frac{g_5}{6} (h^2 - h_1^2)(h^2 - h_2^2)(h^2 - h_3^2). \quad (\text{D1})$$

This configuration corresponds to a (spatially) periodic nonlinear modulation between the heights h_1 and h_2 . The algebra is then somewhat tedious, but with the help of Refs. [45,46] we find Eqs. (22) and (23) given in the text.

The roots h_i are complicated expressions of ϵ and W_0 , but two of them are easily expressed as a function of the third, as $h_1 = h_{m-}$ and $h_3 = h_{m+}$, where

$$h_{m\pm} = \frac{1}{2} \left[\frac{3g_3}{2g_5} - h_2^2 \pm \sqrt{\left(h_2^2 - \frac{3g_3}{2g_5}\right)^2 - 4\left(h_2^4 - \frac{3g_3}{2g_5}h_2^2 - \frac{3\epsilon\beta_{ZZ}}{g_5}\right)} \right]. \quad (\text{D2})$$

This is very well suited to our analysis, because h_2 is the maximum height of the modulated pattern, and thus directly measured.

- [38] From Eqs. (2) and (3), we see that odd powers of $\epsilon^{1/2}$ appear in the power expansion of the distances as even derivatives of Φ and odd derivatives of H . In the expansion of the energy, the odd powers of $\epsilon^{1/2}$ necessarily include odd powers of such terms, and thus they change sign in a parity transformation. Since the resulting equations should be invariant under parity, odd powers of $\epsilon^{1/2}$ in the Lagrangian density should necessarily be in a factor of exact X derivatives, as shown for the $\epsilon^{3/2}$ term in (5).
- [39] E. Infeld and G. Rowlands, *Nonlinear Waves, Solitons and Chaos* (Cambridge University Press, Cambridge, 1990).
- [40] To be more specific, let $\epsilon = \epsilon_{\text{wall}}(1 - \delta^2)$ with $\delta \ll 1$. We obtain that $h(x) \approx dh_{b-}$, to first order in δ , if $x \in [-d \ln \delta/\kappa, d \ln \delta/\kappa]$.

- [41] This justifies *a posteriori* the somewhat uncontrolled approximation in the estimation of the coefficient g_5 .
