We present the experimental realization of a scheme, based on single-photon interference, for implementing superpositions of distinct quantum operations. Its application to a thermal light field (a well-categorized classical entity) illustrates quantum superposition from a new standpoint and provides a direct and quantitative verification of the bosonic commutation relation between creation and annihilation operators. By shifting the focus towards operator superpositions, this result opens interesting alternative perspectives for manipulating quantum states.

PACS numbers: 03.65.Ta, 42.50.Ar, 42.50.Xa

The superposition principle is one of the pillars upon which the entire structure of quantum mechanics is built [1]. A quantum system in a pure state can always be described as a superposition of linearly independent states; thus once one has a quantum system represented by a pure state, the superposition is naturally there. An interbody superposition state, the so-called entangled state, is somewhat trickier to generate than a single-body superposition state. However, it has been demonstrated that entanglement can be achieved by various methods, including a series of unitary operations [2–4] or by postselection of events after unitary operations [5]. On the other hand, the discussion about superpositions of classical mixed states is not as clear as for a pure state [6].

Quantum operators, besides quantum states, play a crucial role in describing physical operations including unitary transformations and measurements in quantum theory. If one can implement a superposition of operators, one can also construct state superpositions by applying the superposed operators to a given state, unless it is a simultaneous eigenstate of the component operations. In fact, also the Schrödinger's cat paradox [7] can be understood as the quantum-mechanical impact of the superposition of macroscopically distinct operations (to kill or not to kill) on a classical object (the cat).

Several groups have recently succeeded in applying simple quantum operators to different quantum states. For example, in the optical domain, basic operations, such as single-photon addition and subtraction, have been demonstrated to produce highly nonclassical [8–11] and non-Gaussian states [12] even when applied to classical states of light [13,14]. Both photon addition and subtraction are performed in a conditional way upon the detection of a single photon in an ancillary (herald) light mode. Sequences of photon additions and subtractions have also

been implemented to show that the two sequences $\hat{a}\hat{a}^\dagger$ and $\hat{a}^\dagger\hat{a}$, where $\hat{a}^\dagger$ and $\hat{a}$ are the bosonic creation and annihilation operators, give different results when applied to the same input light state [15]. This is an important cornerstone for the proof of the bosonic commutation relation

$$[\hat{a}, \hat{a}^\dagger] = \hat{a}\hat{a}^\dagger - \hat{a}^\dagger\hat{a} = \mathbb{1}, \tag{1}$$

which is at the heart of many important consequences of quantum mechanics. However, the complete demonstration of the commutation relation was out of reach because of the lack of an important element in the quantum manipulation toolbox: the possibility of superposing different operators $\hat{A}$ and $\hat{B}$ to form the general operator superposition $\alpha\hat{A} + \beta\hat{B}$, where α and β are complex amplitudes.

Since the superposition principle relies on the indistinguishability among different alternatives, the experimental implementation of quantum operators heralded by a single-photon detection offers a very convenient way to achieve this goal. If the herald field modes of different operators are properly mixed by means of a beam splitter, the information about the origin of a click in the herald photodetector is erased and a coherent superposition of the different operators can be conditionally implemented. Somewhat similar schemes have been recently proposed and experimentally implemented for increasing the entanglement of bipartite Gaussian quantum states by inconclusive photon subtraction [16–18], toward the implementation of a quantum repeater for long-haul quantum communication [19] in ionic systems [20], and for the remote delocalization of a single photon over distinct temporal modes [21].

In this Letter we present the experimental realization of a general scheme, based on single-photon interference, for superposing distinct quantum operations. As recently proposed in Ref. [22], demonstrating the bosonic commutation relation thus reduces to realizing the balanced

superposition $\hat{a}\hat{a}^{\dagger} - \hat{a}^{\dagger}\hat{a}$, and showing that it corresponds to the identity operator $\mathbb{1}$. While most of the mathematical structure of quantum mechanics is based on the commutation relation, this is the first time it is directly probed in an experiment.

The primary laser source is a mode-locked Ti:Sa laser emitting 1.5 ps pulses at a repetition rate of 82 MHz. A rotating ground glass disk (RD) is inserted in the path of the laser beam and a bare single-mode fiber (SMF) is used to collect a portion of the scattered light to provide the pulsed thermal light states [23] of mean photon numbers around unity which have been used as the input states in the experiment. We use a convenient modular scheme (see Fig. 1), where one single-photon addition stage [10] ($\hat{a}^{\dagger}$, based on conditional single-photon parametric amplification in a type-I BBO—β barium borate—nonlinear crystal) is placed between two single-photon subtraction stages [12] [$\hat{a}$, based on the conditional removal of a single photon by adjustable low-reflectivity beam splitters, obtained with combinations of half-wave plates (HWP) and polarizing beam splitters (PBS)].

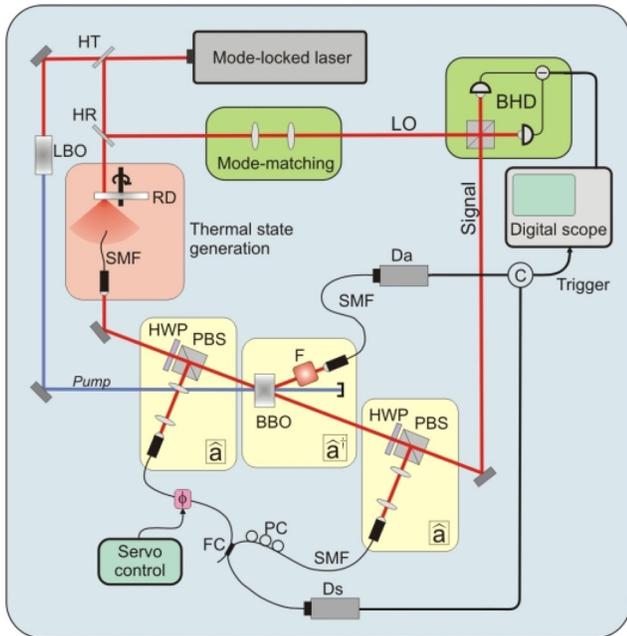

FIG. 1 (color online). Experimental setup. Pump pulses for parametric down-conversion are obtained by frequency doubling the laser output in a LBO—lithium triborate—crystal. The conditionally prepared signal state is mixed with a strong reference coherent field (LO, obtained from a portion of the main laser output) on a 50-50 beam splitter whose outputs are detected by two photodiodes (Hamamatsu PIN S3883). The balanced homodyne detection (BHD) signal is acquired and stored by a digital oscilloscope (Tektronix TDS7104) on a pulse-to-pulse basis triggered by a coincidence (C) between clicks from the Da and Ds single-photon detectors (Perkin Elmer model SPCM AQR-14).

The successful implementation of the desired superposition of operator sequences is determined by the coincidence (C) between a click from the single-photon detector heralding photon addition (Da) and one from a second photodetector (Ds), placed after a -3 db fiber coupler (FC) combining the herald signals from the two subtraction modules. By a click from detector Ds we know that a single photon has been subtracted, but we cannot identify if it was before or after the photon addition. In these conditions, a coincidence event heralds the application of the general operator superposition $\hat{a}\hat{a}^{\dagger} - e^{i\phi}\hat{a}^{\dagger}\hat{a}$ with an adjustable phase ϕ, to any input light field. By varying the phase ϕ with a piezoactuated mirror, any arbitrary balanced superposition of the two operator sequences can be obtained. In particular, by setting $\phi = 0$ or $\phi = \pi$, one can directly implement the commutator or the anticommutator of the creation and annihilation operators, respectively. Note that the present scheme, differently from the original theoretical proposal [22], where only these two possibilities were allowed by using two detectors at both exits of the beam splitter, allows for greater flexibility (by generating operator superpositions with arbitrary relative phases) and experimental simplicity.

Without the click from the addition module ($\hat{a}^{\dagger}$), the scheme reduces to a Mach-Zehnder-type interferometer which can be used to verify the indistinguishability of the two subtraction events by evaluating the visibility of the single-photon interference in the counts at detector Ds. Visibilities of about 97% are obtained by carefully balancing the reflectivity ($\approx 3\%$) of the involved beam splitters, by fine polarization control (PC), and by a precise adjustment of the delays between the corresponding herald modes. If delays are not compensated, only a statistical mixture of the two operator sequences with equal weights is obtained. The Ds count rate is also used to monitor the superposition phase ϕ and lock it to any desired value. The effects of experimental deviations from the ideal realization of this scheme (such as the finite reflectivity of the subtraction beam splitters, the possible multiple photon-pair production in the parametric process, or the fact that real photodetectors are not able to discern the number of photons but only there being photons or not) have already been shown [10,24] not to significantly affect the results of the experiment for the present range of parameters.

The state resulting from the chosen operator superposition is analyzed by means of a high-frequency, time-domain, balanced homodyne detector [25] yielding the distributions of measured field quadratures. Since both the initial thermal states and those resulting from the above manipulations possess no intrinsic phase, the phase of the local oscillator (LO, the reference coherent field for homodyne detection) is not actively scanned, and phase-independent marginal distributions are obtained. However, the final states still clearly depend on the phase ϕ of the superposition. High experimental efficiency is

obtained by minimizing all spurious losses and making sure that all the single-photon operations are performed in exactly the same spatiotemporal mode as the one selected by the LO. This requires narrow spatial and spectral filtering (F) in the herald mode of the parametric down-conversion crystal, and an accurate matching of the fiber-coupled fields reflected from the two subtracting beam splitters to the LO spatial mode.

Figure 2(a) shows a sequence of histograms of raw homodyne data acquired while scanning the phase of the superposition. The remote manipulation of the state by the implementation of different superpositions of creation and annihilation sequences is clearly observed. The quadrature distribution of the final state undergoes a very rapid initial evolution from a bell-shaped curve at $\phi = 0$ towards a volcano-shaped one around $\phi = \pi$, where the phase dependence is much slower. The phase change would not have resulted in such different output states if the operations had been statistical mixtures.

The special cases of $\phi = 0$ and $\phi = \pi$ are illustrated in more detail in Fig. 3, where the Wigner functions of the original thermal state and those resulting from the experimental realization of the commutator and anticommutator between $\hat{a}$ and $\hat{a}^\dagger$ are presented. The fidelity $F = |\mathrm{Tr}\sqrt{\sqrt{\hat{\rho}_{\mathrm{in}}}\hat{\rho}_{\mathrm{out}}\sqrt{\hat{\rho}_{\mathrm{in}}}}|^2$ between the original thermal state and the final one (represented by their reconstructed density operators $\hat{\rho}_{\mathrm{in}}$ and $\hat{\rho}_{\mathrm{out}}$, respectively) is about $F = 0.992$ for the commutator case ($\phi = 0$). This demonstrates that the implemented operator superposition is essentially equivalent to the identity operator. Wigner functions have been obtained from the 10 diagonal density matrix elements (13 for the anticommutator case) reconstructed by means of a maximum likelihood algorithm [26,27] without any correction for the finite detection efficiency. If homodyne detection efficiency ($\eta_d = 0.7$) is corrected for, the

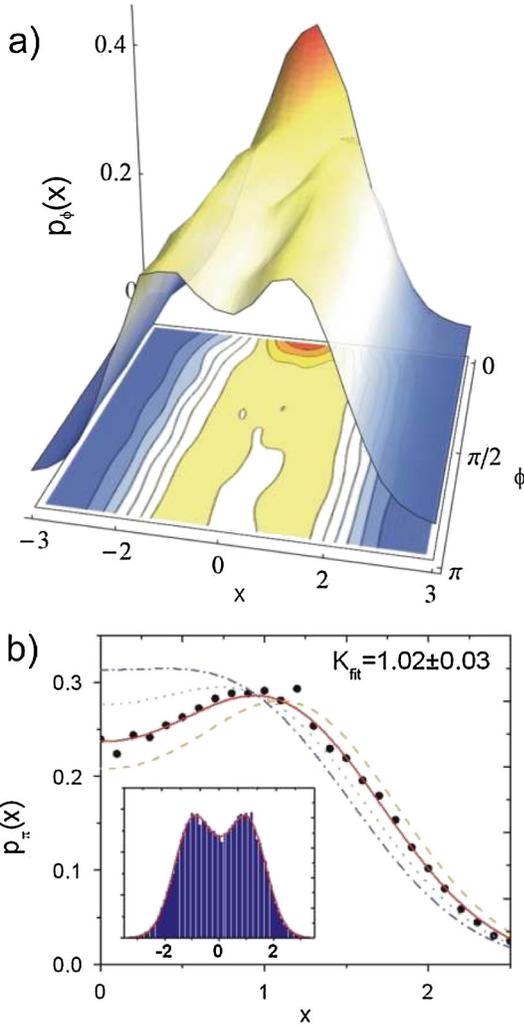

FIG. 2 (color online). (a) Sequence of histograms corresponding to about 250 000 raw quadrature data for the final state as a function of the normalized quadrature x and of the superposition phase ϕ. Data have been obtained in a 16-hour measurement, and have been binned in 9 phase intervals between 0 and π. A thermal field with a mean photon number $\bar{n} = 0.9(1)$ is used as the initial state. (b) Histogram of raw quadrature data (solid dots) for the anticommutator setup at $\phi = \pi$. Also shown are theoretical curves calculated for the actual experimental parameters (total efficiency $\eta = 0.61$, $\bar{n} = 0.9$) and different values of the commutator ($K = 0$: dashed orange; $K = 2$: dotted green; $K = 3$: dash-dotted blue). The solid red curve is the result of the best fit to the experimental data.

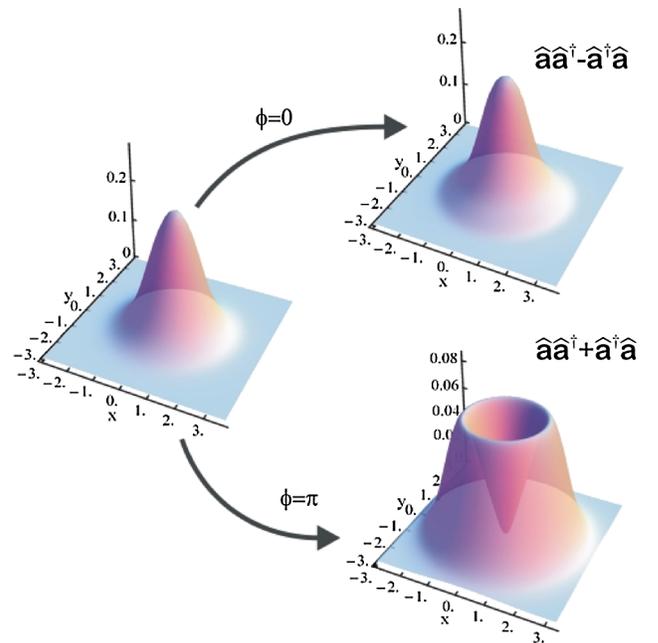

FIG. 3 (color online). Experimentally reconstructed Wigner functions of the original thermal state and of those resulting from the application of the commutator and anticommutator superpositions. The state is not changed for $\phi = 0$. About 10^4 (10^5) quadrature data points have been acquired in the (anti) commutator case.

Wigner function for the state resulting from the anticommutation operator ($\phi = \pi$) clearly attains negative values. The existence of negative regions in the reconstructed Wigner function is a direct signature of the fact that the state impinging on the homodyne detector is highly nonclassical.

Actually, it is interesting to note a fact that was not realized in the theoretical proposal [22]: because of the normalization of quantum states, the above results just demonstrate the commutation relation up to a multiplicative constant K; i.e., one might still have $[\hat{a}, \hat{a}^{\dagger}] = K\mathbb{1}$. However, in this case, the anticommutator setup implements the $2\hat{a}^{\dagger}\hat{a} + K\mathbb{1}$ operator, which produces an output state strongly depending on the exact value of the constant K. Figure 2(b) reports the measured homodyne quadrature distribution for the same initial thermal state after the application of the anticommutation operator ($\phi = \pi$). Also reported are the theoretical distributions calculated for the same experimental parameters but with a few different values of the constant K. Experimental data are consistent with $K = 1$, whereas different integer values are in evident disagreement. A best fit of the experimental homodyne data gives $K = 1.02(3)$, thus quantitatively demonstrating the bosonic commutation relation.

Although the present case only required a coherent superposition of two (sequences of) quantum operators with the same weight, the proposed scheme is much more general and allows one, in principle, to implement coherent superpositions of an arbitrary number of operators with arbitrary relative amplitudes and phases by a network of beam splitters with adjustable reflectivities. The single-photon interference as a way to produce general operator superpositions can be straightforwardly extended to the superposition of $\hat{a}$ and $\hat{a}^{\dagger}$ by letting the creation and annihilation herald photons interfere at a beam splitter. As a representative example, "position" and "momentum" operators in the phase space can be implemented in this way. Our approach can even be generalized to realize various superpositions of higher-order operators in terms of $\hat{a}$ and $\hat{a}^{\dagger}$. Any quantum state can be written as $\sum_n C_n \hat{a}^{\dagger n}|0\rangle$, where C_n are complex amplitudes, and arbitrary states can thus be generated by applying the appropriate superposition of photon creation operators. In this Letter we have experimentally demonstrated a basic building unit for such general operator superpositions on a traveling light field for the first time.
