(Received 23 July 2010; published 8 February 2011)

A complex interaction between turbulence driven $E \times B$ zonal flow oscillations, i.e., geodesic acoustic modes (GAMs), the turbulence, and mean equilibrium flows is observed during the low to high $(L-H)$ plasma confinement mode transition in the ASDEX Upgrade tokamak. Below the L-H threshold at low densities a limit-cycle oscillation forms with competition between the turbulence level and the GAM flow shearing. At higher densities the cycle is diminished, while in the H mode the cycle duration becomes too short to sustain the GAM, which is replaced by large amplitude broadband flow perturbations. Initially GAM amplitude increases as the H -mode transition is approached, but is then suppressed in the H mode by enhanced mean flow shear.

The role of turbulence driven zonal flows (ZFs) in the formation of energy and particle transport barriers is a key issue in many branches of fluid dynamics, particularly in magnetically confined plasmas (e.g., Refs. [[1](#page-3-0)[–3](#page-3-1)]). Fundamental to the creation of transport barriers and the transition to improved plasma confinement states is the reduction of turbulence by flow shearing [\[4](#page-3-2)]. Here, both large-scale mean equilibrium (i.e., pressure gradient ∇P and external momentum driven) $E \times B$ flows and finescale zonal (e.g., turbulent Reynolds stress driven) flows play active, but different, roles [\[5\]](#page-3-3).

Further, ZF models, such as the predator-prey model of Kim and Diamond [[6\]](#page-3-4), suggest a complex interaction between the ZFs, the turbulence, and mean $E \times B$ equilibrium flows. For example, in magnetic confinement fusion devices, before and during the edge transport barrier formation and the transition from low confinement $(L \text{ mode})$ to high confinement $(H \text{ mode})$, the mean flow shear is generally weak so that the geodesic acoustic mode (GAM) (a few kHz coherent ZF oscillation which supplants the more core localized zero-mean-frequency ZF) may provide the dominant shearing effect—perhaps even triggering the shear-flow turbulence suppression feedback loop. As the H mode forms, the mean equilibrium flow shear grows with the steepening edge ∇P and eventually becomes dominant, suppressing both the turbulence and the GAM. This hypothesis is consistent with experimental observations, for example, increased turbulence driven Reynolds stress in the HT-6M tokamak [[7\]](#page-3-5), enhanced low frequency edge turbulence coupling, prior to and during L-H transitions, in the DIII-D tokamak [[8](#page-3-6)], and increased low frequency flow fluctuations in the TJ-II stellarator H mode [\[9\]](#page-3-7). The impact of the mean flow on the ZF-GAM spectrum has also been noted in recent torque (toroidal rotation) scans performed on DIII-D [[10](#page-3-8)]. It is also evident in the fact that the GAM, which is universally observed in Ohmic and additionally heated L-mode regimes, remains suppressed in the H mode [[11](#page-3-9)], even when the edge turbulence level recovers later in H mode due to the steepening edge gradients.

In this Letter we report new measurements from the ASDEX Upgrade tokamak which clearly demonstrate the role and importance of both the oscillating and mean flow shears and their interaction in triggering and maintaining confinement mode transitions in a fusion relevant device. Using microwave Doppler reflectometry to directly measure the $E \times B$ flow and its fluctuations with high spatial (few mm radially) and temporal (submicrosecond) resolution, the buildup of the edge GAM is observed, leading to the onset of sustained limit-cycle oscillations (a feature predicted by predator-prey models) at low plasma collisionalities $\nu^* \propto n_e/T_e^2$ (low plasma density n_e and/or high electron temperature T_e), and finally the suppression of the GAM and turbulence as the mean equilibrium flow shear strengthens. In the limit-cycle phase the presence of a critical threshold for the onset of the turbulence driven flow and the competing turbulence suppression by the flow shear are revealed for the first time.

Doppler reflectometry is a hybrid diagnostic combining the turbulence wave number selectivity of coherent scattering with the radial localization of microwave reflectometry [[12](#page-3-10),[13](#page-3-11)]. Tilting the reflectometer transceiver antennas obliquely to the plasma surface (in a plane perpendicular to the magnetic field) makes the diagnostic sensitive to density fluctuations satisfying the Bragg backscatter condition $k_{\perp} = -2k_0 N_{\perp} \approx 2k_0 \sin \theta_0$, where k_0 is the microwave probing wave number, N_{\perp} the plasma refractive index at the reflection layer, and θ_0 the antenna angle to the plasma surface. The measured fluctuation spectrum $S(f)$ is Doppler shifted $f_D = u_\perp k_\perp/2\pi$ proportional to the fluctuation velocity $u_{\perp} = v_{E \times B} + v_{ph}$ (plasma $E_r \times B$ plus turbulence phase velocity). Generally, $v_{E\times B} \gg v_{\text{ph}}$; hence,

0031-9007/11/106(6)/065001(4) 065001-1 © 2011 American Physical Society

fluctuations in the radial electric field $E_r \simeq -u_{\perp}B$ appear directly in the Doppler shift, while the Doppler peak intensity S_D is proportional to the turbulence level at the probed k_{\perp} [\[11\]](#page-3-9). The measurements reported here were obtained with an X-mode 50–75 GHz tunable frequency reflectometer with 20 MHz signal sampling, located below the tokamak outer midplane [\[14\]](#page-3-12).

GAMs are most clearly observed at low plasma densities and high safety factors $q \mid 15$ $q \mid 15$ due to weaker collisional and Landau damping [[1\]](#page-3-0). Figure [1\(a\)](#page-1-0) shows a GAM existence diagram in terms of net heating power P_{net} versus central line averaged plasma density \bar{n}_e for Ohmic and L-mode heated plasmas. GAMs are not observed in the H mode. Overlaid are the predicted (dashed line) and experimentally measured (curve) L - H power threshold showing two branches; see [\[16\]](#page-3-14) for details. The GAM appears as a coherent peak in the f_D (\tilde{E}_r) spectrum, cf. Fig. [5\(a\)](#page-3-15) in L mode. Note the absence of coherent low frequency ZF activity, either as a peak or broadening of the spectra around zero frequency. The spectra continues to be flat down to the lowest spectral resolution investigated (a few tens of Hz).

From the low density L mode (edge $\nu_{\text{edge}}^* \sim 1$) raising either the heating power or the density causes the turbulence to rise across the whole edge region and to begin pulsating at around 2–4 kHz (sometimes with a slower subpulse activity of a few hundred Hz) with an on-off duty cycle of less than 50%. This intermediate state (labeled I phase) is not transitory but can be maintained for the entire discharge. Observations from many discharges confirm that the L to I phase is a sharp transition with a well-defined threshold, while the full H mode appears to evolve more softly from the I phase. The turbulence pulsing extends across the plasma edge into the open flux surface scrape-off layer (SOL). Figure [2](#page-1-1) shows an example close to the power or density threshold where the discharge dithers between the L and I phases illustrated by the divertor tile shunt current (\propto SOL flow).

FIG. 1 (color online). (a) GAM existence plot in terms of P_{net} vs central line average density. (b) Edge radial electric field E_r profiles for L ($P_{\text{ECH}} = 0.35$ MW) and I phase (1.1 MW) shot 24 811, $B_T = -2.3$ T, $I_p = 0.8$ MA, $q_{95} \sim 4.5$, $\bar{n}_e = 3 \times$ 10^{19} m⁻³, $T_{eo} \sim 2.4$ keV, and favorable lower X point.

The transition from continuous *L*-mode turbulence to pulsing is shown below in the Doppler reflectometer spectrogram $S(f, t)$ from just inside the E_r minimum location at a normalized poloidal flux radius $\rho_{pol} \sim 0.988$. Below are the corresponding (smoothed) traces of the u_{\perp} velocity and fluctuation level S_D at the probed $k_{\perp} \sim 9.8 \text{ cm}^{-1}$.

The u_{\perp} and S_D pulsing are synchronized and display all the features of a limit-cycle behavior with a fast switching between an enhanced and a reduced fluctuation state in less than 1 μ s, i.e., on the turbulence time scale. The GAM is also still present, however, only during the enhanced turbulence state. This is more clearly seen in Fig. [3](#page-2-0) which shows an expanded time trace of (a) the instantaneous E_r (100 ns resolution) plus (b) smoothed E_r and turbulence level S_D traces over four pulses. The figure shows a sequence of events: (1) The turbulence rises between the pulses, (2) reaches a critical threshold (marked by the dashed lines) and triggers an exceedingly large GAM oscillation (3) together with a turbulence driven mean flow—indicated by the offset in the oscillation. [The peak-to-peak GAM flow oscillation amplitude during the pulse can exceed 100% of the mean flow—stronger than in the preceding L mode. While earlier observations also point towards a ∇T_e (drive) threshold for the GAM onset [\[15\]](#page-3-13), it is possible that the GAM is also enhanced by the

FIG. 2 (color online). FIG. 3 (color online). (a) Instantaneous E_r time trace over several pulses showing GAM oscillation, plus (b) smoothed E_r and turbulence level S_D showing (1) rising turbulence, (2) threshold, (3) GAM, and (4) turbulence suppression for shot 24 906.

mean flow. Note also that the pulse frequency is generally less than a quarter of the GAM frequency, so generally only a couple of GAM periods are visible.] Then (4), the resultant enhanced flow shearing affects the turbulence, which now begins to reduce. On reaching the critical threshold (there may be some hysteresis) the GAM switches off and the mean E_r well disappears, and in this case even reverses to become positive. This represents a substantial cyclic variation in the $E_r \times B$ flow. Figure [1\(b\)](#page-1-0) shows the cyclic variation in the E_r profile (*I* high and *I* low) for a typical discharge with $P_{\text{ECH}} = 1.1$ MW electron cyclotron heating power, together with an L-mode phase (0.35 MW). There is no equivalent modulation in the electron pressure gradient ∇P_e . Similar poloidal flow reversal observations were recently observed using gas-puff imaging on NSTX tokamak just prior to the L-H transition [[17\]](#page-3-16).

On the equilibrium time scale (i.e., milliseconds) the enhanced turbulence driven flow (deeper edge negative E_r well) supports a stronger edge pressure gradient, and hence higher energy confinement factors. In this discharge there is a steepening of the edge T_e gradient but no evident H-mode pedestal formation. Note also the inward movement of the E_r well (minimum) position and the consequent steepening of the positive and negative E_r shear regions. This E_r well movement is typical with improving energy confinement in L - as well as H -mode conditions.

The role of the GAM shearing is demonstrated in Fig. [2\(d\)](#page-1-2) with estimates of the mean flow shearing rate $\tau_M^{-1} = \Delta u_\perp/L_r$ (red points) where Δu_\perp is the flow veloc-ity step across the shear layer [[4](#page-3-2)] and L_r the radial turbulent eddy size (correlation length approximated by the negative shear layer width), the corresponding flow oscillation shearing rate $\tau_o^{-1} = \sigma_{u\perp}/L_r$ (gray shaded curve) where $\sigma_{u\perp}$ is the flow standard deviation, together with the turbulence decorrelation rate τ_c^{-1} (open blue points) from the Doppler amplitude fluctuations. The horizontal bars

FIG. 4 (color online). Evolution of (a) GAM frequency, (b) GAM amplitude A_{GAM} and u_{\perp} flow velocity with heating power shot 24 751; $B_T = -2.4$ T, $I_p = 1.0$ MA, $q_{95} \sim 4$, $\bar{n}_e =$ $2.6 \times 10^{19} \text{ m}^{-3}$, $T_{eo} \sim 3 \text{ keV}$, $P_{\text{ECH}} = 0.6 \text{ MW}$ plus P_{NBI} ramp. (c) Evolution of GAM amplitude profile during L-I-H mode transition, plus E_r well position (arrows) in shot 24 750.

indicate the averaging period. The $\sigma_{u\perp}$ tends to overestimate the effective GAM shearing in L mode, but underestimates the GAM peak-to-peak amplitude during the I-phase pulses. Note that all three parameters are local, i.e., nonpoloidally averaged, estimates at the same tokamak measurement location, and that the turbulence τ_c^{-1} is dominated by the probed k_{\perp} . Nevertheless, the figure shows that both the mean and oscillatory shear rates are well below the turbulence τ_c^{-1} in L mode but converge with the onset of the pulsing. Of the two, it is τ_o^{-1} which exceeds τ_c^{-1} and then subsequently tracks it—thus maintaining the limit-cycle behavior.

The (equilibrium time scale) GAM amplitude initially increases with heating power. This is shown in Figs. [4\(a\)](#page-2-1) and [4\(b\)](#page-2-1) where a neutral beam injection (NBI) power ramp is applied in addition to the background ECH power. The GAM amplitude A_{GAM} (peak-to-peak velocity [[15](#page-3-13)]) averaged over 100 ms, close to the GAM inner zonal boundary, begins to increase with the onset of the I phase 50% dutycycle pulsing, coincident with a bifurcation in the GAM frequency and the mean $E \times B$ flow ramping. However, the GAM eventually decreases as the mean flow shear strengthens. This effect is shown more clearly in Fig. [5.](#page-3-17) Here the ECH power is higher at 1.4 MW and the I-phase transition is triggered earlier at 1.65 s by the density ramp. The mean E_r well depth jumps from -5.5 to -8.9 kV m^{-1} with a corresponding increase in the energy confinement factor $H_{98} = \tau_E / \tau_E$ scale from 0.6 (L) to 0.7 (I). In Fig. [5\(b\)](#page-3-15) the f_D spectrum (14 ms averaged) shows a weaker GAM peak, although the GAM during the pulse remains stronger than the 3 kHz pulse perturbation. Around 2.37 s, the pulsing begins to diminish and clear, but weak edge-localized-mode-free, *H*-mode T_e and T_i temperature pedestals form. The D_{α} emission drops slightly (reduced particle recycling) and the mean E_r well deepens, reaching -24.5 kV m^{-1} with $H_{98} \approx 0.8$ indicating a transition to

FIG. 5 (color online). Time averaged f_D spectra for (a) L , (b) I-, and (c) H-mode phases around E_r minimum at ρ_{pol} = 0.988, plus (d) , (e) parameter traces and (f) shearing rates of shot 24 750; $B_T = -2.3$ T, $I_p = 1.0$ MA, $q_{95} \sim 4$, $\bar{n}_e = 2.8 \times$ 10^{19} m⁻³, $T_{eo} \sim 5$ keV, $P_{ECH} = 1.4$ MW plus P_{NBI} ramp, lower single null with favorable ∇B X-point direction.

a mean flow shear dominated regime. This is confirmed by the local shear rate estimates shown in Fig. $5(f)$ where the rising mean flow τ_M^{-1} crosses the turbulence decorrelation rate coincident with the crossing of the diminishing oscillatory τ_o^{-1} shear rate. At this point a GAM is no longer observed anywhere in the edge region. There is also a qualitative change in the density turbulence behavior, which drops across the edge and becomes more intermittent with short, semirandom pulses. In Fig. [5\(c\)](#page-3-15) the intermittency peak rises to 5.5–6 kHz and the duty cycle drops to less than 30%. Essentially the turbulence pulses become too short to sustain a complete GAM period. Overall, the GAM disappears into a rising spectral background; i.e., the $E_r \times B$ flow spectral power moves out of the coherent GAM into enhanced random broadband flow fluctuations [[13](#page-3-11)].

With increasing mean flow shear the radial zonal extent of the GAM is also reduced. Figure [4\(c\)](#page-2-1) shows the A_{GAM} radial profile evolution for the same discharge as in Fig. [5.](#page-3-17) As the confinement improves, the E_r well moves inward as it deepens (indicated by the arrows at the respective times), coinciding with the outer extent of the GAM eroding, before it disappears below the rising background level (dashed line). The GAM is only observed in the negative E_r shear region, which again shows the link between the mean and oscillating flows.

Finally, with increasing plasma density both the GAM and limit-cycle or pulse frequencies decrease—the GAM due to decreasing T_e and the cycle most likely due to collisional ZF damping [[2\]](#page-3-18). To date, the limit-cycle pulsing has not be observed for the high density L-H threshold branch, i.e., $\bar{n}_e > 5 \times 10^{19} \text{ m}^{-3}$. Although the GAM can be just as intense here, its reduced frequency relative to the pulse might effectively close out the I-phase regime leading to a more rapid transition to the H mode.

To summarize, evidence is presented of the GAM-ZF mean flow—turbulence interaction where the GAM flow shearing dominates in the turbulent, low mean flow shear L mode, but is suppressed in the quiescent, high mean flow shear H mode. In between, at low plasma density a limitcycle oscillation forms with competing turbulence drive and enhanced flow shearing. With increasing input power the GAM amplitude first rises, but is then suppressed and radially eroded by the increasing mean flow shear. The picture is of close interaction and interdependence of the equilibrium and turbulence driven flows—which acting together appear to trigger the velocity shear feedback loop believed to be responsible for the H-mode formation. In the H mode the coherent GAM is replaced by broadband flow fluctuations, which may also play a role in decorrelating the turbulence [\[18](#page-3-19)].

We thank E. Poli for assistance with the beam-tracing software and G. Tynan, P. Diamond, R. McDermott, B. Scott, and K. Hallatschek for fruitful discussions.
