Crooker ² ¹Chemistry Division, Los Alamos National Laboratory, Los Alamos, New Mexico 87545, USA ²National High Magnetic Field Laboratory, Los Alamos, New Mexico 87545, USA (Received 8 March 2011; published 3 August 2011)

We report magnetophotoluminescence studies of strongly quantum-confined 0D diluted magnetic semi-conductors (DMS), realized in $\mathrm{Mn^{2^+}}$ -doped ZnSe/CdSe core-shell colloidal nanocrystals. In marked contrast to their 3D (bulk), 2D (quantum well), 1D (quantum wire), and 0D (self-assembled quantum dot) DMS counterparts, the ubiquitous yellow emission band from internal d-d ($^4T_1 \rightarrow ^6A_1$) transitions of the $\mathrm{Mn^{2^+}}$ ions in these nanocrystals is *not* suppressed in applied magnetic fields and *does* become circularly polarized. This polarization tracks the $\mathrm{Mn^{2^+}}$ magnetization, and is accompanied by a sizable energy splitting between right- and left-circular emission components that scales with the exciton- $\mathrm{Mn}\,sp$ -d coupling strength (which, in turn, is tunable with nanocrystal size). These data highlight the influence of strong quantum confinement on both the excitation and the emission mechanisms of magnetic ions in DMS nanomaterials.

DOI: 10.1103/PhysRevLett.107.067402 PACS numbers: 78.67.Bf, 61.46.Df, 71.55.Gs, 75.50.Pp

The coupling between band electrons and local magnetic moments underpins many fascinating phenomena in condensed matter physics. In semiconductors, these couplings are simply realized and often studied in diluted magnetic semiconductors (DMS) [1–3], where the strong sp-d exchange interactions between electron-hole spins and the embedded magnetic atoms (typically Mn) can lead, for example, to giant exciton g factors, magnetic polarons, or carrier-mediated ferromagnetism in both II-VI and III-V materials. To address how sp-d interactions are affected-and potentially controlled-by quantum confinement and wave-function engineering, advances in molecular-beam epitaxy (MBE) and colloidal synthesis have focused considerable attention on DMS systems of reduced dimensionality: 2D quantum wells, 1D wires, and 0D epitaxial dots and (even smaller) nanocrystals. Recent studies indicate substantial influence arising from even single Mn atoms [4–7], and suggest that the sp-d exchange "constants" themselves can be modified [8–10].

A defining feature of wide-gap $A_{1-x}^{II}Mn_xB^{VI}$ DMSs $(E_g \gtrsim 2.2 \text{ eV})$ is a prominent yellow photoluminescence (PL) band centered at \sim 2.1 eV, that originates from internal $({}^4T_1 \rightarrow {}^6A_1)$ transitions within excited $3d^5$ shells of the Mn²⁺ ions [1,2]. That is, a band-edge exciton can either recombine radiatively with rate k_R , or transfer its energy to a Mn²⁺ ion via an Auger-like process (described below) with rate $k_{\rm Mn}$ that depends on the exciton-Mn coupling. It is known that at low temperatures and in magnetic fields, this Mn²⁺ PL band is suppressed and remains unpolarized, while the band-edge exciton PL increases and circularly polarizes. This universal behavior has been observed in DMS crystals, epilayers, quantum wells, quantum wires, and in epitaxial quantum dots [1,2,11-18]. To date however, the magneto-optical and polarization properties of this Mn²⁺ PL have not been reported in colloidal DMS nanocrystals, despite widespread technological interest in their use as efficient phosphors [19] or spintronic materials [20] and despite being materials that evince the strongest quantum confinement and potentially largest exciton-Mn coupling.

Here we measure the magneto-PL properties of $\mathrm{Mn^{2^+}}$ -doped ZnSe/CdSe core-shell colloidal nanocrystals. In stark contrast to their 3D (bulk), 2D (quantum well), 1D (wires and rods) and even their 0D (epitaxial quantum dot) DMS counterparts, the yellow $\mathrm{Mn^{2^+}}$ PL band in these nanocrystals is *not* suppressed in applied magnetic fields and *does* develop a sizable circular polarization. This polarization tracks the magnetization of the embedded $\mathrm{Mn^{2^+}}$ atoms, and is accompanied by an unexpectedly large energy splitting between right- and left-circular PL components that scales with the overall strength of the sp-d interaction (which, in turn, we tune with CdSe shell thickness). These data highlight the critical role of strong quantum confinement on both the excitation and the emission of $\mathrm{Mn^{2^+}}$ atoms in DMS nanomaterials.

Mn²⁺-doped ZnSe/CdSe core/shell nanocrystals (NCs) were grown using colloidal methods [5,21]. All ZnSe cores have 17 Å radii. Five doping levels yielded cores averaging $\langle n_{\rm Mn} \rangle = 0.8, 1.6, 2.6, 5.2, \text{ and } 9.6 \, {\rm Mn}^{2+} \, {\rm ions/core} \, ({\rm average})$ Mn concentration up to $\sim 2\%$), as determined by inductively coupled plasma optical emission spectroscopy. Nonmagnetic (undoped) cores were also grown. Ensembles of cores were then overcoated with CdSe shells of thickness $0-6(\pm 2)$ Å, which reduces quantum confinement and lowers the NC band-edge from 3 eV to \sim 2.4 eV. Nonresonant magneto-PL was measured using weak 3.06 or 3.81 eV laser excitation (100 μ W/cm²) in the Faraday geometry $(\mathbf{B} \parallel \mathbf{k})$, with dilute NC films mounted in the variable-temperature insert of a 8 T magnet. Importantly, magnetic circular dichroism (MCD) spectroscopy was also performed on all films to measure the Zeeman splitting of the 1S (band-edge) exciton absorption peak. All Mn-doped NCs show enhanced Zeeman splittings that follow Brillouin ($B_{5/2}$) functions, indicating strong sp-d coupling of the bands to the paramagnetic, spin-5/2 Mn²⁺ ions [5,10,20]. This provides an independent measure of the Mn²⁺ magnetization within a given NC sample and allows us to compare the overall strength of the sp-d interaction between samples. Quantum confinement and sp-d coupling fall rapidly with increasing shell thickness as previously observed [10]; however, these NCs do not exhibit sp-d inversion since the NC band-edges did not fall below \sim 2.4 eV.

To most clearly present the new aspects of the $\rm Mn^{2+}$ PL from these NCs, we first show, by way of comparison, the characteristic magneto-PL from a traditional wide-gap II–VI DMS. Figure 1(a) shows PL from a $\rm Zn_{.92}Mn_{.08}Se$ epilayer grown by MBE. At 0 T, the broad $\rm Mn^{2+}$ PL band is clearly visible at \sim 2.1 eV, as is the PL from exciton recombination at the 2.8 eV band edge. With applied magnetic field the $\rm Mn^{2+}$ PL is rapidly and equally suppressed in both σ^{\pm} circular polarizations [Fig. 1(b)], while the exciton PL increases many-fold and becomes completely σ^{+} polarized. We observed similar behavior in a variety of other DMS epilayers and quantum wells.

This behavior—a suppression of the unpolarized Mn²⁺ PL and an enhancement and polarization of the exciton PL—is a universal characteristic of all nonresonant magneto-PL studies of DMS materials reported to date, aspects of which have been reported in bulk crystals [1,2,11–13], in quantum wells [14], quantum wires [15], and in "self-assembled" epitaxial quantum dots [16–18]. Although the precise mechanism of energy transfer from excitons to the Mn^{2+} $3d^5$ shell is still debated [13,14,18,22], its marked field dependence indicates a spin-dependent excitation transfer as detailed by Nawrocki [22] and later refined by Chernenko [18]. The relevant selection rules require that energy transfer conserves the spin projection of the Mn + exciton system along **B**, $S_z^{\text{Mn}} + s_z^{\text{ex}}$. Using standard notation [1,2], the spin-aligned ground state of the half-filled $Mn^{2+} 3d^5$ shell $(^{6}A_{1})$ has total spin $S^{Mn} = 5/2$, while the lowest crystalfield-split excited states $({}^4T_1, {}^4T_2, {}^4A_1, {}^4E)$ have one flipped spin and therefore $S^{\rm Mn}=3/2$. Applied fields Zeeman split these levels [inset, Fig. 1(b)]. "Bright" excitons (with total spin+orbital angular momentum projection $J_z = \pm 1$) have $s_z^{\rm ex} = 0$, and therefore they *cannot* excite Mn²⁺ out of $S_z^{\rm Mn} = \pm 5/2$ levels. However, the -5/2 level becomes predominantly populated as the paramagnetic Mn²⁺ polarize in applied magnetic fields. Concurrently, in the Faraday geometry, excitons rapidly populate the lowest $J_z = +1$ bright state [1]. These effects suppress the exciton-Mn energy transfer rate $k_{\rm Mn}$ and therefore suppress (enhance) the Mn²⁺ (exciton) PL. In contrast, "dark" $(J_z = \pm 2)$ excitons have $s_z^{\text{ex}} = \pm 1$ and can excite the $S_7^{\text{Mn}} = -5/2$ ground state; this explains why, e.g., PL intensities in epitaxial dots are relatively

unaffected in the Voigt geometry ($\mathbf{B} \perp \mathbf{k}$, $\mathbf{B} \perp$ dot axis), where bright and dark excitons become mixed [18].

Once the $\mathrm{Mn^{2+}}\ 3d^5$ shell is excited, relaxation to the 4T_1 level proceeds quickly [18]. From this point, however, radiative transitions to the 6A_1 ground state are nominally spin forbidden. However, weak spin-orbit couplings of the 4T_1 levels soften these selection rules [1,2], allowing phonon-assisted $\mathrm{Mn^{2+}}\ \mathrm{PL}$ at $\sim 2.1\ \mathrm{eV}$.

In marked contrast to the conventional behavior just described, Figs. 1(c) and 1(d) show magneto-PL from Mn:ZnSe/CdSe nanocrystals. At zero field, only the Mn²⁺ PL band is visible—exciton PL is entirely quenched (undoped but otherwise identical NCs do show strong exciton PL at ~ 2.7 eV; not shown). Thus, energy transfer from excitons to the Mn²⁺ ions is quite efficient in these NCs even though the average Mn concentration is <1%. More importantly, the Mn²⁺ PL band is *not* suppressed in applied magnetic fields—rather, it develops a pronounced circular polarization of $\sim 30\%$. To our knowledge, this behavior has no precedent in any nonresonant PL study of $A_{1-x}^{II} Mn_x B^{VI}$ materials reported to date [1,2,11–18]. These data therefore provide a first indication that, in contrast to typical DMS materials, the Mn²⁺ PL from DMS nanocrystals is more than merely a byproduct of exciton-Mn energy transfer. Rather, the data point different character of both the Mn²⁺

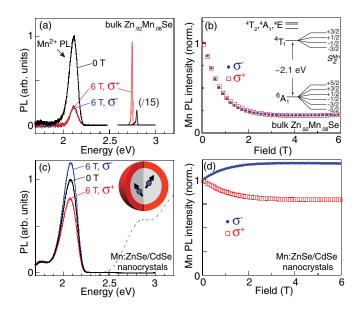

FIG. 1 (color online). (a),(b) Magneto-PL from bulk ZnMnSe at 4 K, showing conventional DMS behavior. The yellow ${}^4T_1 \rightarrow {}^6A_1$ Mn²⁺ PL at ~2.1 eV is suppressed by magnetic fields and remains unpolarized, while 2.8 eV exciton PL (scaled down 15 ×) increases. Similar behavior is found in 3D, 2D, 1D, and 0D DMS grown by MBE. (c),(d) The contrasting magneto-PL from Mn:ZnSe/CdSe nanocrystals ($\langle n_{\rm Mn} \rangle = 2.6$ Mn/core; T=1.8 K). The Mn²⁺ PL is *not* suppressed by magnetic fields, and *does* develop a sizable circular polarization (and, exciton PL never appears). The dashed line shows the NC absorption.

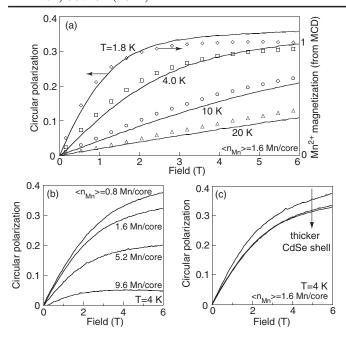

FIG. 2. (a) The circular polarization (CP) of the $\mathrm{Mn^{2+}}$ PL from Mn:ZnSe/CdSe nanocrystals versus field and temperature (lines; left axis). CP tracks the Brillouin-like $\mathrm{Mn^{2+}}$ magnetization (independently measured by MCD; points, right axis). (b) CP(B) for different $\langle n_{\mathrm{Mn}} \rangle$ (all NCs have similar CdSe shells). (c) CP(B) for NCs with different CdSe shell thickness (all cores have $\langle n_{\mathrm{Mn}} \rangle = 1.6$).

excitation and emission process in strongly quantum-confined systems which, as elucidated below, can actually be used to reveal spin physics and *sp-d* interactions in nanoscale DMS materials.

We note that these new findings are unrelated to the circularly polarized *exciton* PL reported in large Mn:CdSe NCs [20]. By design, excitons in large Mn:CdSe NCs have energies <2.1 eV, so that energy transfer to the Mn²⁺ does not occur. Thus, exciton PL remains unquenched and, in keeping with traditional DMS, becomes circularly polarized.

It is also evident in Fig. 1(c) that exciton PL at the NC band-edge never appears in applied magnetic fields to 6 T (and even in ultrahigh fields to 55 T; not shown). Again, this stands in marked contrast to conventional DMSs [1,2,11–18], where band edge PL increases dramatically with field because the exciton-Mn²⁺ energy transfer rate $k_{\rm Mn}$ is suppressed. Thus, exciton-Mn energy transfer remains surprisingly efficient in these NCs, even when the Mn^{2+} are completely polarized ($S_7^{Mn} = -5/2$). This contrast with conventional DMSs likely originates not only in the strong exciton-Mn coupling that exists in colloidal NCs, but also in the essential role played by dark excitons (which, as described above, can excite Mn ions regardless of S_7^{Mn}). Specifically, (i) dark excitons may already be the preferred ground state in applied fields since the s-d exchange constant is likely inverted in these NCs [8,10], (ii) ground-state (i.e., dark) excitons in NCs have very small radiative rates at low temperatures ($k_R \ll k_{\rm Mn}$) [23], and (iii) even if bright excitons have lower energy, the random NC orientation mixes bright with dark excitons since **B** will seldom lie along preferred angular momentum quantization axes.

Importantly, Fig. 2 reveals that the circular polarization of the Mn²⁺ PL follows the paramagnetic (Brillouin-like) magnetization of the spin-5/2 Mn²⁺ ions. The circular polarization, CP = $(I^{\sigma^+} - I^{\sigma^-})/(I^{\sigma^+} + I^{\sigma^-})$ (solid line, left axis), scales with the temperature- and field-dependent Mn²⁺ magnetization (symbols, right axis), which was independently measured in this same NC ensemble via MCD spectroscopy. Studies of NCs with different Mn doping [Fig. 2(b)] indicate that CP is largest ($\sim 40\%$) at the lowest Mn doping, but drops as $\langle n_{\rm Mn} \rangle$ increases to 9.6 Mn/core, where Mn-Mn interactions become increasingly probable. Furthermore, Fig. 2(c) shows that for NCs with fixed $\langle n_{\rm Mn} \rangle$ but increasing CdSe shell thickness, CP is relatively unaffected. Together, these data suggest that polarized Mn PL arises primarily from isolated Mn²⁺ in the ZnSe cores, but is not particularly influenced by the overall NC size.

Perhaps most interestingly, and again in contrast to conventional DMS materials, we find that the Mn²⁺ PL exhibits a sizable energy splitting, ΔE , between σ^{\pm} components [see Fig. 3(a)]. Fitting the uppermost 25% of the PL to a Gaussian line shape, we report here the center wavelength. Significantly, Fig. 3(b) shows that ΔE does not increase linearly with field. Rather, ΔE exhibits a characteristic Brillouin-like dependence on field and temperature, that once again is proportional to the Mn²⁺ magnetization within any given NC sample (subtracting field-independent PL backgrounds prior to fitting does not change ΔE appreciably). As such, ΔE saturates by only a few Tesla at low temperatures—but at large values of order 5-10 meV, which greatly exceeds the typical linear Zeeman shifts expected of Mn²⁺ $3d^5$ levels $(g_{Mn} \simeq 2.0 \equiv$ 60–300 $\mu eV/T$).

Moreover, while ΔE is found to be largely independent of $\langle n_{\rm Mn} \rangle$, it *does* depend on the degree of quantum confinement in these core-shell NCs, which we can tune by varying the CdSe shell thickness. Figure 3(c) shows ΔE measured in a series of NCs with identical Mn:ZnSe cores, but with increasing CdSe shell thickness. While still following a Brillouin function, the saturation amplitude of ΔE is considerably reduced when the CdSe shell is thicker. Crucially, the reduction in ΔE is almost perfectly echoed by the similar reduction of the sp-d coupling strength in the same three samples (as measured by MCD via the 1S Zeeman splitting). As shown previously [10], thicker CdSe shells cause the conduction- and valence-band wave functions to occupy larger volumes, thereby reducing their overlap with the embedded Mn²⁺ ions and reducing the overall sp-d interaction strength—in this way the sp-d coupling can be independently tuned in these NCs while

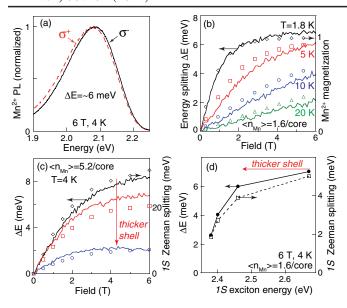

FIG. 3 (color online). (a) Normalized σ^{\pm} Mn²⁺ PL from Mn:ZnSe/CdSe NCs at 6 T, showing an energy splitting ΔE . (b) ΔE (lines; left axis) scales with the Mn²⁺ magnetization in this sample (points, right axis, from MCD). (c) Using NCs with identical Mn:ZnSe cores but increasing CdSe shell thickness to 6 \pm 2 Å, ΔE tracks the 1S exciton Zeeman splitting (from MCD), indicating that ΔE scales with the net sp-d coupling strength. (d) A similar comparison, in the $\langle n_{\rm Mn} \rangle = 1.6$ Mn/core NCs.

leaving the Mn doping unchanged. A similar agreement is observed in the other NC series; Fig. 3(d) compares the saturated (6 T) values of ΔE and 1S Zeeman splitting for the $\langle n_{\rm Mn} \rangle = 1.6$ series. Again, both are reduced by the same factor as the sp-d coupling is reduced by increasing CdSe shell thickness. These data demonstrate that ΔE provides a reliable and independent measure of sp-d coupling in strongly quantum-confined DMS systems.

We note finally that neither CP nor ΔE was found to be influenced by the polarization of the excitation light, even when resonantly pumping the 1S exciton peak with a tunable laser—the Mn PL evidently retains little memory of the exciton's initial spin orientation.

We turn now to the possible origins of the $\mathrm{Mn^{2^+}}$ PL polarization and energy splitting. Early studies of Mn:ZnS NCs revealed fast Mn PL decays [24], prompting suggestions that quantum confinement enhances hybridization between s, p bands and Mn d electrons. This point of view was later clarified [25,26]: multiexponential PL decays are a generic feature of $A_{1-x}^{\mathrm{II}}\mathrm{Mn}_xB^{\mathrm{VI}}$ DMS regardless of dimensionality. We measured $\sim 100~\mu\mathrm{s}$ PL decays in our NCs (independent of **B**), which is not atypical for dilute $\mathrm{Mn^{2^+}}$ in ZnSe. Nonetheless, the circular polarization and (especially) the confinement-dependent ΔE both point to a coupling of the Mn $3d^5$ electrons with the NC's conduction and valence bands, beyond that typically found in more weakly-confined DMS materials. Related

conclusions can also be drawn from the recent discovery that excitons can organize magnetic polarons in colloidal Mn:CdSe NCs, even at quite high temperatures [27]. While awaiting a formal theoretical underpinning of these effects, we anticipate that studies of single Mn-doped NCs will help unravel the nature of this coupling, as will measurements of ultrafast exciton dynamics as a function of NC size, **B**, and Mn²⁺ doping. The role of any excess charge in these NCs, and how it may influence the polarization and energy of Mn²⁺ emission, also merits investigation [28].

In summary, these studies reveal that the processes of both $\mathrm{Mn^{2^+}}$ excitation and $\mathrm{Mn^{2^+}}$ emission are essentially different in colloidal DMS nanocrystals as compared to conventional DMS materials. Magnetic fields do not suppress the efficient exciton-Mn energy transfer, implicating the potential role of dark excitons in these NCs. Further, the circular Mn PL polarization and unexpectedly large energy splitting (that scales with sp-d coupling strength) highlights the critical influence of strong quantum confinement and suggests their use as powerful probes of spin interactions in nanoscale DMS materials.
