Research Center Optimals, Technische Universität Universitation, 6766 Entertainern, Germany<br>(Received 24 May 2011; published 14 October 2011)

We measure the temporal pair correlation function  $g^{(2)}(\tau)$  of a trapped gas of bosons above and below<br>setticed temperature for Boso Einstein condensation. The measurement is performed in situ by using a the critical temperature for Bose-Einstein condensation. The measurement is performed in situ by using a local, time-resolved single-atom sensitive probing technique. Third- and fourth-order correlation functions are also extracted. We develop a theoretical model and compare it with our experimental data, finding good quantitative agreement. We discuss, finally, the role of interactions. Our results promote temporal correlations as new observables to study the dynamical evolution of ultracold quantum gases.

DOI: [10.1103/PhysRevLett.107.160403](http://dx.doi.org/10.1103/PhysRevLett.107.160403) PACS numbers: 03.75.Hh, 03.75.Kk, 05.30.Jp

The intriguing effect of particle bunching was first observed in a seminal experiment by Hanbury Brown and Twiss, where they studied correlations among pairs of photons coming from a chaotic source [\[1\]](#page-3-1). The result, which could be explained in terms of classical waves, had a difficult route to be accepted under a particle perspective. The full quantum theory, due to Glauber [[2\]](#page-3-2), signaled the birth of quantum optics and made the formalism, with all its physical content, available for massive particles. Over the years, analogous Hanbury Brown– Twiss experiments were performed with electrons [[3\]](#page-3-3), neutrons [\[4](#page-3-4)], and cold atoms [\[5](#page-3-5)[,6](#page-3-6)]. The possibility to extract information about the quantum statistics and the coherence, paved by the Hanbury Brown–Twiss experience, conjugated with the capabilities of deriving the temperature and the spatial order [\[7](#page-3-7)], contributed to make this technique one of the most powerful to probe atomic systems. The quest to understand the behavior of more and more complex samples suggests its application to the study of strongly interacting 1D gases [[8](#page-3-8)[,9\]](#page-3-9), disordered [\[10\]](#page-3-10) and supersolid phases [\[11\]](#page-4-0), and to identify nontrivial excitations [\[12\]](#page-4-1). While first-order correlations are often accessible via interference experiments, higher-order correlations require in general the recording of density or atom number fluctuations by a probe sensitive enough to detect single particles (counting techniques) or, at least, atomic shot noise (absorption imaging). In order to have a good statistical description, an average over many realizations of the system (in theory all possible realizations) is needed. Consequently, correlations, especially at orders higher than two, are usually difficult to measure because of the huge statistics required for a reliable signal. Only in some limited cases can intrinsic processes in a quantum gas such as photoassociation or three-body losses be used as a sensitive probe for higher-order correlations at zero distance [\[13](#page-4-2)[,14\]](#page-4-3). The direct observation of third-order correlations is still challenging and, by using standard techniques, requires a considerable effort in data collection and analysis [\[15\]](#page-4-4). In this, like in the great majority of the abovementioned experiments with ultracold gases, correlations have been studied only in the spatial domain, whereas the temporal counterpart has been very poorly explored, limited only to the characterization of atomic beams [[5,](#page-3-5)[16\]](#page-4-5). Boosted by recent achievements [[17](#page-4-6)–[19](#page-4-7)], spatially resolved single-atom sensitive detection methods can give direct access to higher-order correlation functions in situ. Such experiments are not complicated by the time-of-flight expansion and directly manifest the properties of the manybody system. Moreover, if the detection method is only locally probing the system, even time-resolved correlation measurements are possible.

In this Letter, we report on the first observation of temporal thermal bunching of ultracold bosonic atoms in a trap. Using scanning electron microscopy as a timeresolved local detection method, our measurements directly yield the second-, third-, and fourth-order time correlation functions. Notably, due to the spatially resolved measurement and due to the possibility to follow the dynamics of the system, our technique is effectively an original method for characterizing ultracold quantum systems, in both space and time. All these features can turn out to be extremely useful in providing deep insight into the dynamics of strongly correlated many-body quantum systems [\[20\]](#page-4-8).

The general form of the normalized spatiotemporal correlation function of *n* particles at position  $\mathbf{r}_i$  at time  $t_i$ , with  $i = 1, \ldots, n$ , is given by

<span id="page-0-0"></span>
$$
g^{(n)}(\mathbf{r}_1, t_1; \dots; \mathbf{r}_n, t_n)
$$
  
= 
$$
\frac{\langle \hat{\Psi}^{\dagger}(\mathbf{r}_1, t_1) \dots \hat{\Psi}^{\dagger}(\mathbf{r}_n, t_n) \hat{\Psi}(\mathbf{r}_n, t_n) \dots \hat{\Psi}(\mathbf{r}_1, t_1) \rangle}{\langle \hat{\Psi}^{\dagger}(\mathbf{r}_1, t_1) \hat{\Psi}(\mathbf{r}_1, t_1) \rangle \dots \langle \hat{\Psi}^{\dagger}(\mathbf{r}_n, t_n) \hat{\Psi}(\mathbf{r}_n, t_n) \rangle}, (1)
$$

where  $\hat{\Psi}$  are the bosonic operators and  $\langle \ldots \rangle$  indicates the ensemble average. We first derive an analytical expression of  $g^{(1)}(\mathbf{r}_1, t_1; \mathbf{r}_2, t_2)$  for an ideal Bose gas at temperature T<br>above the critical temperature T tranned in a harmonic above the critical temperature  $T_c$ , trapped in a harmonic potential  $V(\mathbf{r}) = m\omega^2r^2/2$ , with average trapping frequency  $\omega$ , extending the approach of Ref. [\[21\]](#page-4-9) to take into account also the temporal evolution. Given  $\tau = t_2 - t_1$  and  $\mathbf{r} = \mathbf{r}_2 - \mathbf{r}_1$  and assuming  $\omega \tau$ ,  $\hbar \omega / (\bar{k}_B T) \ll 1$ , we obtain

$$
g^{(1)}(\mathbf{r},\tau) = \frac{1}{(1 + i\frac{\tau}{\tau_c})^{3/2}} \exp\left(-\frac{mr^2}{2\hbar\tau_c^2} \frac{\tau_c + i\tau}{1 + (\frac{\tau}{\tau_c})^2}\right),\tag{2}
$$

where  $\tau_c = \frac{\hbar}{k_B T}$  is defined as the correlation time. From the above expression, we can derive any higher-order correlation function for thermal bosons, and, in particular, the second-order correlation can be easily calculated as  $g^{(2)}(\mathbf{r}, \tau) = 1 + |g^{(1)}(\mathbf{r}, \tau)|^2$ . The time correlation function<br> $g^{(2)}(0, \tau)$  can be interpreted as the probability to detect a  $g^{(2)}(0, \tau)$  can be interpreted as the probability to detect a particle a time  $\tau$  after another particle at the same position particle a time  $\tau$  after another particle at the same position  $(r = 0)$ . For a thermal cloud of bosons this function decreases from 2 to 1 on a time scale related to the correlation time  $\tau_c$ . A value of the pair correlation function higher than 1 indicates bunching of thermal bosons in time. For a coherent source like a Bose-Einstein condensate (BEC), we expect instead  $g^{(2)}(0, \tau) = 1$  for any  $\tau$  [\[21](#page-4-9)], i.e., a flat detection probability in  $\tau$ detection probability in  $\tau$ .

Since our setup has been described earlier [[22](#page-4-10),[23](#page-4-11)], we briefly illustrate the experimental procedure we have followed to measure the atomic correlation functions. The key feature of our experiment is a scanning electron microscope which is implemented on a standard apparatus for the production of ultracold quantum gases. The measurement principle is based on the electron impact ionization of the atoms with subsequent ion detection. A sketch of the working principle is depicted in Fig. [1.](#page-1-0) In addition to a spatial resolution of better than 150 nm, the technique is

<span id="page-1-0"></span>

FIG. 1 (color online). (a) Schematic of the apparatus. The electrons of the focused beam collide with atoms leading to ionization with a probability of 40%. The ions are guided to the detector to be counted. The average count rate is  $1700$  counts/s. (b) The electron-atom interaction volume is defined by the electron beam itself and by the extension of the cloud along the z axis. (c) A typical measurement of the ion signal showing the first 20 bins.

characterized by a sequential detection method with temporal resolution of 100 ns. Thus, time-dependent quantities such as the second- or higher-order correlation functions  $g^{(n)}(\tau)$ ,  $n = 2, 3, \ldots$ , become experimentally accessible.<br>To prepare the atomic sample we load approximately To prepare the atomic sample we load approximately  $1.5 \times 10^{6}$  <sup>87</sup>Rb atoms from a magneto-optical trap in a  $CO<sub>2</sub>$  dipole trap. The atoms are then evaporatively cooled above or below the critical temperature. We can typically prepare cold thermal samples of  $2-3 \times 10^5$  atoms at 150 nK as well as BECs of up to  $1 \times 10^5$  atoms in the  $F = 1$  hyperfine ground state. Since integration along the probing line reduces the correlation signal amplitude (see, for example, [\[6\]](#page-3-6)), after the evaporation we compress the cloud along the direction of the electron beam by adiabatically transferring it to a *light sheet* dipole trap. This trap is realized by means of a focused elliptical 852 nm laser beam, with waists  $(6.5, 130) \mu$ m. We then completely switch off the CO<sub>2</sub> tran and the sample is held by the light switch off the  $CO<sub>2</sub>$  trap, and the sample is held by the light sheet alone for all the duration of the measurements (Fig. [1](#page-1-0)). The final frequencies, for a beam power of 3 mW, are  $\omega_{x,y,z} \approx 2\pi \times (9, 20, 413)$  Hz. To detect the atoms, an electron beam of 6 keV energy, 20 nA current, and 120 nm FWHM is focused at the center of the cloud, where the atom density and hence the number of ions produced are maximal. This choice is only meant to allow for a reduced number of experimental cycles, but any other point of the cloud can be investigated as well. The electronatom interaction is confined within a volume set by the electron beam transverse profile and by the vertical extension of the atomic cloud (Fig. [1\)](#page-1-0). The ions produced by electron impact ionization are collected in a channeltron. For each bin of 10  $\mu$ s we record the number of ions<br>detected and the absolute detection time, as shown in the detected and the absolute detection time, as shown in the inset in Fig. [1](#page-1-0). In a typical measurement of 600 ms duration we extract  $\sim$  1000 ions. We note that this procedure leads to a negligible perturbation of the system [\[24\]](#page-4-12). After the measurement, the remaining atoms are released from the trap and imaged after time of flight to extract the temperature. In order to optimize the signal-to-noise ratio, we compute the correlation functions over about 1500 repetitions of the experiment.

From Eq. [\(1](#page-0-0)), integrating on the absolute time and averaging on the different repetitions of the experiment, we calculate the correlation function  $g^{(2)}(\tau)$  for a cold<br>thermal cloud. In Fig. 2, we report the measurements for thermal cloud. In Fig. [2,](#page-2-0) we report the measurements for two different temperatures  $T = 45$  nK and  $T = 100$  nK. The temperature at which a condensate fraction starts to be visible, for  $P = 3$  mW power in the light sheet, is around 40 nK. In both measurements, we can clearly observe bunching. In these data plots we have omitted the first two bins, which show an abnormally high value of  $g^{(2)}(\tau)$ . These points are affected by extra ion counts introduced by the electronics of the detector. As a test for introduced by the electronics of the detector. As a test for the procedure, we apply the same technique to a reference measurement which is a priori uncorrelated. This is

<span id="page-2-0"></span>

FIG. 2 (color online). Normalized second-order temporal correlation function. Data (dots) acquired at different temperatures (circles for 45 nK, squares for 100 nK) are plotted together with the fitting functions (lines) explained in the text. The inset displays the data (diamonds) acquired for a BEC and the corresponding fit (line). Please note that even well below the critical temperature (the thermal fraction cannot be detected in time-of-flight absorption imaging) we are able to measure a small residual bunching induced by the thermal component.

obtained by probing a thermal cloud at  $T = 230$  nK with an electron beam of waist well larger than the correlation length. As expected, no bunching signal is detectable in the measurement, making sure that what we have observed in the data sets taken in standard conditions is genuine thermal bunching.

Averaging over several experimental cycles, fluctuations in the total number of detected ions affect the normalization of the correlation function. As a result, an offset shifts the uncorrelated signal to a value 1% above 1. To compensate for these fluctuations we normalize  $g^{(2)}(\tau)$  by the factor  $1 + \sigma^2 / \langle N \rangle^2$  where  $\sigma^2$  and  $\langle N \rangle$  are respectively factor  $1 + \sigma^2 / \langle N \rangle^2$ , where  $\sigma^2$  and  $\langle N \rangle$  are, respectively, the variance and the mean value of the total number of the variance and the mean value of the total number of detected ions in the different experimental realizations. A measurement with a BEC is also presented in the inset in Fig. [2.](#page-2-0) Notably, we can still detect a small correlation signal due to a residual thermal fraction present well below the critical temperature  $T_c$ . The  $g^{(2)}(\tau)$  data points are fitted<br>with the function we derived for an ideal noninteracting with the function we derived for an ideal noninteracting gas of bosons integrated over the volume, leaving the amplitude and  $\tau_c$  as free parameters (lines in Fig. [2](#page-2-0)). The results of the fits are shown in Fig. [3](#page-2-1), where the extracted correlation times are plotted as a function of the temperature of the sample. Since we cannot derive the temperature for a cloud with more than 70% condensate fraction by time-of-flight measurements, in the plots of Fig. [3](#page-2-1) we indicate as the BEC temperature the average temperature between zero and the coolest measurable temperature of 30 nK. The agreement between the experimental data and the theoretical function  $\tau_c = \hbar/(k_B T)$  is fairly good.

<span id="page-2-1"></span>

FIG. 3 (color online). Correlation time  $\tau_c$  as a function of the temperature. The values obtained by fitting the experimental data (circles) are compared with the function  $\tau_c = \hbar/(k_B T)$  (line). The inset shows the fitted bunching enhancements (circles for thermal gases and a triangle for the BEC) and the corresponding theoretically expected values for the noninteracting (solid line) and the interacting (dashed line) model. Each curve segment refers to a different power of the dipole trap ( $P = 3, 4, 5$  mW).

Hence, this technique can be proposed as a local probe for the temperature of ultracold samples, especially when standard imaging techniques fail.

In the inset in Fig. [3,](#page-2-1) we show the fitted amplitude of the normalized second-order correlation functions at different temperatures together with the values expected from the volume integration of the noninteracting model and of its extension to the interacting case [[21](#page-4-9)]:

$$
g_{\text{int}}^{(2)}(\mathbf{r},0) = 1 + \frac{2a^2}{r^2} + |g^{(1)}(\mathbf{r},0)|^2 \left(1 - \frac{4a}{r}\right), \quad (3)
$$

a being the s-wave scattering length. As expected [[21\]](#page-4-9), repulsive interactions play a role for in situ measurements, since they induce short-range antibunching that reduces or overcomes the bunching signal of bosons. The inclusion of interactions in our model contributes in shifting the theoretical prediction towards the range of compatibility with the experimental results. By far, the main contribution to the reduction of the bunching excess to the maximum value of 6% comes from integration along the direction of the electron beam where the extension of the cloud is bigger than typical correlation lengths of our samples. In the regime where the BEC fraction is dominant, the signal is further reduced by the presence of a large coherent component in the integrating volume [[25](#page-4-13)] and by the role of interactions in the condensate.

In addition, we also calculate the third-order correlation function, extracting it from the same data sets for which we derived the  $g^{(2)}(\tau)$ . Bunching is expected to be more<br>propounced at higher orders *n* as a consequence of the pronounced at higher orders  $n$  as a consequence of the

<span id="page-3-11"></span>

FIG. 4 (color online). Normalized third-order correlation function (dots) along the axis ( $\tau_1 = t_2 - t_1$ ,  $\tau_2 = t_3 - t_1 = 2\tau_1$ ) for a thermal cloud with  $T = 100$  nK. The solid line is the fitting function explained in the text.

factorial law *n*! that regulates the dependence of the correlated to the uncorrelated amplitudes. For this reason, higher-order correlations can be employed as a highly sensitive test for coherence, with the only drawback represented by the need of high statistics, as proved by the very few experiments reporting correlations at orders higher than 2.

In Fig. [4](#page-3-11), we show an example of the third-order correlation function  $g^{(3)}(\tau_1, \tau_2)$ , obtained for the data<br>set at  $T = 100 \text{ pK}$  along the axis  $(\tau_1, \tau_2 = 2\tau_1)$ . The solid set at  $T = 100$  nK, along the axis ( $\tau_1$ ,  $\tau_2 = 2\tau_1$ ). The solid line in the picture is a fit made with the volume integration of the noninteracting model  $g^{(3)}$ <br> $\log(1)(\pi/2) = \log(1)(\pi/2) = \log(1)(\pi - \pi/2)$ noninteracting model  $g^{(3)}(\tau_1, \tau_2) = 1 +$  $|g^{(1)}(\tau_1)|^2 + |g^{(1)}(\tau_2)|^2 + |g^{(1)}(\tau_2 - \tau_1)|^2 + 2\Re[g^{(1)}(\tau_1 - \tau_1)]^2$  $(\tau_1)$ <br>the  $g^{(1)}(-\tau_2)g^{(1)}(\tau_2-\tau_1)$ ], along the same axis, leaving the amplitude as the only free parameter. The measured amamplitude as the only free parameter. The measured amplitudes of the third-order correlation functions  $g^3(0, 0)$  – 1 are  $0.14 \pm 0.07$  and  $0.10 \pm 0.02$ , respectively, for the data sets at  $T = 45$  nK and  $T = 100$  nK. Our measurements show that the amplitudes of the  $g^{(3)}$  correlations are also affected by repulsive interactions, since the bare volume integration of the noninteracting model is not sufficient to explain the observed reduction of the signal. Interestingly, the corresponding ratios  $\lceil g^{3}(0, 0) 1\frac{|g^2(0) - 1|}{\sqrt{g^2(0)} - 1}$ , which are  $3.2 \pm 2.4$  and  $5.0 \pm 2.2$ , show instead agreement, within the errors, with the values derived from the noninteracting model: 4.2 and 2.8. This result is in accordance with the seminal work on the three-body losses [\[14\]](#page-4-3) and may signal that the effect of interactions does not scale with the order of the correlation function. Finally, we measured the fourth-order correlation function amplitude: For  $T = 45$  nK,  $g^{(4)}(0, 0, 0) - 1 = 0.46 \pm 0.42$  and for  $T = 100$  nK  $g^{(4)}(0, 0, 0) = 1$  $0.46 \pm 0.42$  and for  $T = 100$  nK,  $g^{(4)}(0, 0, 0) - 1 = 0.23 \pm 0.05$  At times longer than  $\tau$ , the  $g^{(4)}$  correlation  $0.23 \pm 0.05$ . At times longer than  $\tau_c$ , the  $g^{(4)}$  correlation signals drop, respectively, to the values of  $0.8 \pm 0.1$  and  $1.03 \pm 0.01$ . The evaluation of  $g^{(4)}$  correlations turns out to be strongly affected by the poor statistics, thus rendering any comparison with theory difficult. Further investigation on fourth- and higher-order correlations can be, however, useful to identify the influence of interactions in multipleparticle bunching.

In summary, we have observed temporal pair correlations in a cold gas above  $T_c$ . We have measured  $g^{(2)}(\tau)$  for different temperatures of the atoms and compared the different temperatures of the atoms and compared the results with a theoretical model that we derived for a noninteracting and for an interacting system of thermal bosons. A measurement on a BEC has also revealed a minimal bunching compatible with the presence of a residual thermal fraction. A signal of third- and fourth-order correlations has been derived from the same data. The amplitudes of the bunching enhancement of  $g^{(3)}$  and  $g^{(2)}$  correlations are slightly affected by repulsive interparticle interactions, while their ratios are compatible, within the error bars, with a noninteracting modelization. The electron microscopy technique, which we use, represents a powerful, fast, and efficient way to measure correlations, with the possibility to probe the system in space and time and particularly suited for systems of reduced dimensionality. Notably, pair correlations in time can give access to the dynamical structure factor and reveal, in contrast to static pair correlations, the dynamical properties of the quantum system.

- <span id="page-4-12"></span>[24] The measurement procedure is leading to 5% atom loss, which is indeed a negligible perturbation in the regimes we worked in, i.e., a BEC well below  $T_c$  and a thermal gas. Moreover, heating due to the measurement is monitored by separately analyzing the ion signal in the first and in the last 300 ms of measurement. The temperatures derived by the measured second-order correlation function for these two subsystems show no differences.
