(Received 2 July 2013; published 29 October 2013)

We demonstrate the feasibility of levitating a small mirror using only radiation pressure. In our scheme, the mirror is supported by a tripod where each leg of the tripod is a Fabry-Perot cavity. The macroscopic state of the mirror is coherently coupled to the supporting cavity modes allowing coherent interrogation and manipulation of the mirror motion. The proposed scheme is an extreme example of the optical spring, where a mechanical oscillator is isolated from the environment and its mechanical frequency and macroscopic state can be manipulated solely through optical fields. We model the stability of the system and find a three-dimensional lattice of trapping points where cavity resonances allow for buildup of optical field sufficient to support the weight of the mirror. Our scheme offers a unique platform for studying quantum and classical optomechanics and can potentially be used for precision gravitational field sensing and quantum state generation.

Recently much effort has been directed toward the development of new fabrication methods and experimental techniques for controlling optomechanical interactions at the quantum level  $[1-6]$  $[1-6]$  $[1-6]$ . Optomechanical effects have been observed in mechanical objects with masses ranging from femtograms, as in nano-opto-mechanical systems [[7\]](#page-4-3), to kilograms in the case of gravitational wave antennas [[8\]](#page-4-4). The interest in these systems stems from their suitability for a range of applications including precision measurement [[9](#page-4-5)], creation of a mechanical quantum harmonic oscillator  $[1,10-12]$  $[1,10-12]$  $[1,10-12]$  $[1,10-12]$ , control of quantum macroscopic coherence [[13](#page-4-8)], the generation of squeezed light for quantum information  $[14, 15]$  $[14, 15]$  $[14, 15]$ , reversible mapping of quantum states of light into mechanical excitations [[16](#page-4-11)], tests of large-scale quantum decoherence [\[17\]](#page-4-12), and probing models of gravity [[18](#page-4-13),[19](#page-4-14)]. The main barrier to reaching the quantum regime is thermalization resulting from intrinsic coupling to environmental reservoirs. This is generally hard to avoid since most mechanical oscillators are supported by some mechanical structure that acts as a bridge for thermal fluctuations. One method to limit thermalization is to operate in cryogenic environments. Nevertheless, the dissipation of energy through the mechanical support still contributes significantly to the decoherence of the mechanical state [[20](#page-4-15)]. Fabrication of a phononic-band gap structure into the substrate [[21](#page-4-16)] has been proposed as one way to reduce the dissipation. Optical trapping [\[22\]](#page-4-17) and levitation [\[23–](#page-4-18)[27](#page-4-19)] have also been suggested as possible routes to low-dissipation quantum optomechanics.

In this paper we propose a new approach toward reaching the quantum-optomechanical regime. We consider a vertical geometry where the upper cavity mirror floats on the radiation pressure exerted by intra-cavity fields, as shown in Fig. [1.](#page-0-0) As with other levitation proposals [\[23–](#page-4-18)[27\]](#page-4-19), this system eliminates thermal coupling through material supports. The crucial difference is that the levitation is scattering-free, and the mirror is supported only by modes of the high-finesse cavities underneath the mirror. This coherent coupling between the mirror motion and the optical field means that the motion of the mirror is imprinted into the cavity modes that support the mirror without any added noise. This opens the door to fully

<span id="page-0-0"></span>

FIG. 1 (color online). Arrangement of the tripod optical cavity with the convex end mirror levitated on the three optical springs. The three lower mirrors are identical:  $q_1$ ,  $q_2$ , and  $q_3$  are the centers of curvature of the three lower mirrors; cavity lengths  $L_0$ allowed by this configuration for optical stability are between 17 and 20 cm.

coherent control of the mirror motion, better allowing preparation of quantum states. Furthermore, since the restoring force that holds the mirror in position is fully optical, the spring constant and damping coefficient will be selectable through choice of optical frequency and power.

Optical forces and stability.— The optical spring effect has been observed in various systems [\[28–](#page-4-20)[30](#page-4-21)] where the measured mechanical resonant frequency ( $\omega_m$ ) depends on the optical power. We propose to create an optical spring, not just to provide additional rigidity to a weak mechanical spring, but to actually support a cavity mirror using radiation pressure alone. Stable suspension of the mirror can be attained through the use of a tripod-beam configuration shown in Fig. [1.](#page-0-0) Each beam will be the fundamental mode of a high-finesse cavity formed between the levitated mirror and one of the fixed lower mirrors. Appropriate use of active or passive damping, combined with the optical spring effect, will stabilize the suspended mirror on the optical fields.

The optical spring mirror that we propose is a convex mirror with radius of curvature of  $R_t = 3$  cm and diameter of 2 mm that is coated with high reflective dielectric materials and has reflectivity of 99.98%–99.998%. Such high-reflective coatings typically have a laser damage threshold  $\approx 30 \text{ MW/mm}^2$ , much greater than the intensity anticipated on the mirror. The mirror substrate is made out of fused silica and has a mass around 0.3 mg. The three lower mirrors are high-reflective coated with 99.8%–99.98% reflectivity and have radius of curvature  $R_b = 20$  cm. The cavity decay rate is given by  $\kappa =$  $\pi c/(fL_0)$ , where  $L_0$  is the mean length of the cavity,<br>and  $\mathcal F$  is the cavity finesse and  $\mathcal F$  is the cavity finesse.

The full position and orientation of the upper mirror is defined by the position of its centre of curvature  $r$ , which we write in Cartesian coordinates  $\{x, y, z\}$ , and the z-x-z Euler angles  $\{\alpha, \beta, \gamma\}$  that define its orientation from the canonical position. The orientations of the three lower mirrors are defined by the position of their centers of curvature  $\mathbf{q}_n$ , where  $n = 1, 2, 3$  refers to the three cavities. The optical cavities form between the center of curvature of the upper mirror and the centers of curvature of the lower mirrors, with lengths  $L_n = R_b - R_t + ||\mathbf{q}_n - \mathbf{r}||$ .<br>The less power *R* inside each equity is given by *R* = The laser power  $P_n$  inside each cavity is given by  $P_n =$  $P_n^{(in)} \mathcal{F}/[1+\mathcal{F}^2 \sin^2(kL_n)],$  where  $k = 2\pi/\lambda$ ,  $\lambda$  is the uncurrent and  $P_n^{(in)}$  is the input power of the legal driving wavelength and  $P_n^{(in)}$  is the input power of the laser driving that cavity. This circulating power translates into a force  $\mathbf{F}_n$ on the mirror with magnitude  $F_n = 2P_n/c$ . A total power of approximately 3 W in the three cavity beams combined, a near-paraxial geometry, and cavity finesse of 1000 will give a force sufficient to suspend the mirror. When the mean radiation pressure force cancels the gravitational pull on the mirror any variation in the intracavity power can produce a damping or restoring force, depending on the cavity field detuning. If we consider a case where each cavity field is blue-detuned from the resonance condition, any shortening of the cavity will result in an increase of power and therefore of the radiation pressure force, and lengthening of the cavity will result in a decrease of the force. This suggests that there will be a restoring force allowing the floating mirror to be stable for small fluctuations.

The mechanical stability is best analyzed by constructing a generalized potential  $U(\mathbf{r}, \alpha, \beta, \gamma)$  for the six coordinates describing the top mirror. This potential is independent of  $\alpha$  and  $\gamma$ , and trivially stable with respect to  $\beta$ . Setting  $\beta = 0$ , it is given by

$$
U = \sum_{n=1}^{3} \frac{2P_n^{(\text{in})}}{c} \frac{\tan^{-1}[\mathcal{F} \tan(kL_n(\mathbf{r}))]}{k} + mgz.
$$

For displacements of the top mirror there is a large, threedimensional lattice of similar tight-confinement spots. The potential near the trapping sites is visualized in Fig. [2](#page-1-0), where we see isopotential surfaces in (a), showing that the stable region can be up to 30 nm wide in the horizontal directions, and approximately 1 nm wide along the  $\zeta$  axis. In the  $xy$  plane there is a triangular lattice of trap sites approximately 15  $\mu$ m apart, as shown in part (b). In parts (c) and (d) we see 2D sections of the potential near a central trapping site. The potential depths of these trapping sites scale almost linearly with the finesse and input

<span id="page-1-0"></span>

FIG. 2 (color online). (a) Isopotential surfaces showing the stability region in space. (b) Triangular lattice of trap sites showing the trapping potential of the mirror on  $x-y$  with trapping sites spaced from each other by approximately 15  $\mu$ m. The potential is in logarithmic scale, normalized to its value just outside of the traps,  $U_0$ . (c)–(d) Trapping potential on y-z and x-y around the tight-confinement region. For these plots a finesse of 1000, a total input power of 3 W, and a mirror mass of 0.3 mg were used.

power of the cavities; however, increasing the finesse also reduces the spatial size of the traps in each dimension. Tuning the frequency of the three beams to find the equilibrium point could prove very effective, as very small fractional changes in the laser frequency of each cavity enable scanning of the entire lattice to reach the trapping site. Optical stability is obtained when the mirror is precisely positioned at one of the equilibrium points, corresponding to a cavity detuning of  $\kappa/2$ , and the cavity length will then be self-locked by the radiation pressure gradient. In principle, no active feedback is required to keep the cavity stable, although it may nevertheless be desirable. The optical spring stiffness tensor can be calculated by taking the second derivative of the work done on the mirror [\[31\]](#page-4-22), and from it the mechanical frequency can be determined. Figure  $3(a)$  shows the  $\vec{z}$  axis frequency for four choices of finesse, as a function of trapping beam detuning.

While the blue-detuned field (trapping beam of detuning  $\delta_1$ ) will create a strong trapping force, it will also result in some antidamping force on the mirror [[8](#page-4-4),[32](#page-4-23)]. To counteract this we use a second, red-detuned field with detuning  $\delta_2$ . When the cavity linewidth is less than the mechanical resonance frequency of the mirror ( $\kappa \ll \omega_m$ ), a laser tuned to the red motional sideband of the cavity will amplify the scattering of light into the main cavity mode, thus removing energy from the mirror [[33](#page-4-24)[–35\]](#page-4-25). The detuning of the cooling beam needs to be equal to the mechanical frequency of the mirror,  $\delta_2 = -\omega_m$ , which depends on finesse<br>as well as the detuning of the transition beam from the as well as the detuning of the trapping beam from the cavity resonance.

Background gas collisions.—Background gas collisions with the mirror can increase or decrease the mechanical energy of the mirror depending on its size. Assuming that the mirror operates in the free molecular flow regime [[36\]](#page-4-26), the mechanical dissipation rate due to fluid friction is given by  $\gamma_m = 2\rho_g v_g S/m$ , where m is the mass of the mirror, S its cross section,  $\rho_g$  is the density of gas, and  $v_g =$  $\sqrt{2k_B T/m_g}$  is the mean of the magnitude of the velocity

<span id="page-2-0"></span>FIG. 3 (color online). (a) Plot of the mechanical frequency of the mirror on the optical spring versus cavity detuning of the trapping beam normalized to the cavity linewidth for four different cavity finesses (from darkest to lightest,  $\approx 1000$ , 3000, 5000, and 10 000). (b) Minimum mean phonon number plotted as a function of cavity finesse. Both fields are considered, with detuning  $\delta_1 = 0.5 \kappa$  for the trapping beam and  $\delta_2 = -\omega_m$  for the cooling beam, and with the former being ten times more the cooling beam, and with the former being ten times more powerful than the latter.

of a gas molecule of mass  $m<sub>g</sub>$  at temperature T in any one dimension. For regularly available pressures  $P$  lower than  $10^{-8}$  bar, a dissipation rate lower than  $10^{-5}$  Hz is estimated, which suggests a mechanical  $O$  factor greater than  $10^{10}$  for a mechanical frequency of 500 kHz. Since the mechanical  $Q$  of the levitated mirror is not limited by intrinsic mechanical dissipation, lowering the pressure will linearly enhance the *Q* factor.

Assuming a gas molecule undergoing an elastic collision with the mirror, the collision rate can be written as  $\Gamma_{g}(v_{g}) = PSv_{g}/(k_{B}T)$ . The energy dissipation rate of the mirror can be calculated by

$$
\frac{dE_g}{dt} = \int_0^\infty dv \Gamma_g(v) D(v) \frac{2m_g^2}{m} v^2,\tag{1}
$$

where  $D(v)$  is the Maxwell-Boltzman velocity distribution. Neglecting the dissipation and noise sources due to blackbody and laser power fluctuations (described below), one can estimate the thermal phonon numbers  $\langle n_{\text{th}} \rangle$  =  $\dot{E}_g/(\gamma_m \hbar \omega_m)$  to be around 50 for a vacuum pressure of  $10^{-8}$  hars. This is already a low initial phonon number 10-<sup>8</sup> bars. This is already a low initial phonon number occupation that can be further reduced by laser cooling.

Laser noise.—Laser intensity noise causes fluctuation of the optical spring constant. To determine the antidamping rate arising because of this we follow a similar method as taken in the context of trapping atoms in optical traps [[37](#page-4-27),[38](#page-4-28)].

Fluctuations in the intracavity photon number alter the mechanical frequency of the trap. We shall focus on stochastic fluctuations of the optical spring stiffness. The dominant parametric heating rate,  $R_{n\rightarrow m}$ , arises from the component of the noise power spectrum at the second harmonic. The rate of transition for the cavity mirror from a state with *n* phonons to a state with  $m \neq n$ phonons during a time period of  $\tau$  is only nonzero when  $m = n \pm 2$  and can be simplified as  $R_{n \to n\pm 2}$  $(\pi \omega_m^2/16)S_{\epsilon}(2\omega_m)(n+1 \pm 1)(n \pm 1)$ , where  $S_{\epsilon}(\omega) = 2/\pi \int_{-\infty}^{\infty} d\tau' \cos(\omega t'/\epsilon(t))/\epsilon(t + t')$  is the one-sided power  $2/\pi \int_0^{\infty} dt' \cos \omega t' \langle \epsilon(t) \rangle \langle \epsilon(t + t') \rangle$  is the one-sided power<br>spectrum of the fractional fluctuation and  $\epsilon(t)$  is fractional spectrum of the fractional fluctuation, and  $\epsilon(t)$  is fractional intensity noise.

We can see that the shot noise leads to parametric transitions (where the phonon number  $n \rightarrow n \pm 2$  jumps in pairs) at a rate proportional to the power spectral density of the fluctuations at frequency  $2\omega_m$ . The heating rate due to intensity fluctuations is given by

$$
\gamma_I = \frac{\sum_n p_n (R_{n \to n+2} - R_{n \to n-2})}{\sum_n p_n \hbar \omega_m (n+1/2)} = \frac{\omega_m^2}{4} S_{\epsilon} (2\omega_m), \quad (2)
$$

where  $p_n$  is the probability that the mirror occupies a state with  $n$  phonons. The average energy increases exponentially with an e-folding time of  $\tau_e = \gamma_I^{-1}$ . Assuming a mirror oscillation frequency of 500 kHz an energy mirror oscillation frequency of 500 kHz, an energy e-folding time of 10 s requires  $S_{\epsilon} \approx 1.3 \times 10^{-6} \text{ Hz}^{-1}$ .<br>Hence if most of the intensity noise were evenly Hence, if most of the intensity noise were evenly

Blackbody radiation.— A small fraction of the light incident on the mirror will be absorbed due to its finite absorption coefficient, and with no means of mechanical dissipation in vacuum the only way to dissipate this energy is through blackbody radiation [\[39\]](#page-4-29). A fraction of the absorbed light results in increasing the internal temperature of the mirror,  $T_{\text{int}}$ .

The internal heating rate is given by  $dE_{\text{abs}}/dt = \sum \hbar c k R_{\text{abs}}(k)$ , where  $R_{\text{abs}}$  is the blackbody absorption rate and the sum is over all blackbody radiation modes (and polarizations),  $k$  is the wave vector of each mode. The total energy absorption rate is given by

$$
\frac{dE_{\rm abs}}{dt} = \frac{S}{4\pi^2} \int_0^\infty dk \hbar c^2 k^3 n_k \epsilon_b = \frac{\pi^2 S \epsilon_b (k_B T)^4}{60c^2 \hbar^3}, \tag{3}
$$

where  $n_k = 1/(e^{\hbar c k / k_B T} - 1)$  is the probability occupation<br>of each mode  $\epsilon$ , is the temperature-independent blackof each mode,  $\epsilon_h$  is the temperature-independent blackbody emissivity of the mirror. The blackbody emission rate is then given by  $-dE_{\text{abs}}/dt$  where  $T \rightarrow T_{\text{int}}$ . Taking into<br>account the blackbody absorption and emission as well as account the blackbody absorption and emission as well as laser absorption heating, a temperature raise of  $\Delta T_b < 1\,$  K can be inferred for an absorption coefficient  $\alpha =$  $10^{-5}$  m<sup>-1</sup> and  $\epsilon_b \approx 2 \times 10^{-4}$  [\[40\]](#page-4-30). We note that the net<br>work done by blackbody radiation on the mirror over one work done by blackbody radiation on the mirror over one oscillation is zero due to the time-independent nature of the radiation.

Optical cooling.—Now we investigate the possibility of cooling the mirror close to its quantum ground state even when starting from room temperature. It has been shown that for sufficiently high mechanical frequencies cooling in cryogenic devices is sufficient [[3\]](#page-4-31), although the ground state can also be achieved using laser cooling [\[5\]](#page-4-32).

In the resolved sideband regime, where the frequency of the resonator is greater than the cavity linewidth, a laser field red-detuned from the cavity resonance frequency by the mechanical frequency will result in cooling of the motion of the mirror. This is because the cavity will enhance process whereby a phonon from the mirror is added to the photon, giving light that is resonant with the cavity mode. We can add such a laser field to our system; however, the cooling achieved is limited by the heating due to the trapping beam, which is blue-detuned from cavity resonance. Denoting the trapping and cooling beams as  $\lambda = \{1, 2\}$ , respectively, we can write the net laser cooling rate of the mirror due to both intracavity fields as [\[33,](#page-4-24)[34\]](#page-4-33),  $\gamma_{\rm rp} = G^2 \sum_{\lambda=1,2} [S_{\lambda}(-\omega_m) - S_{\lambda}(+\omega_m)],$  where  $G = \frac{1}{\sqrt{2\pi\omega_m^2} \sqrt{I_{\lambda}^2 + I_{\lambda}^2}}$  $\omega_c \sqrt{\hbar/(2m\omega_m)}$ / $L_0$  is the optomechanical coupling,  $\omega_c$  is the cavity resonance frequency  $S_2(\omega) = \bar{\pi} \times 2\pi/(k\omega^2)^2 + \pi^2$ the cavity resonance frequency,  $S_{\lambda}(\omega) = \bar{n}_{\lambda} \kappa / [(\kappa/2)^2]$ <br>  $(\omega + \delta)^2$  is the nower spectrum of the laser noise and  $(\omega + \delta_{\lambda})^2$  is the power spectrum of the laser noise, and  $\bar{n}_{\lambda}$ <br>is the mean photon number of the optical field Jonoring all is the mean photon number of the optical field. Ignoring all other sources of damping, one can write an expression for the mean thermal phonon occupation

$$
\frac{\langle n \rangle_{\min} + 1}{\langle n \rangle_{\min}} = \frac{S_1(+\omega_m) + S_2(+\omega_m)}{S_1(-\omega_m) + S_2(-\omega_m)}.
$$
 (4)

In a typical optomechanical system, the minimum phonon number attained by laser cooling is  $\langle n \rangle_{\text{min}} \approx (\kappa/4\omega_m)^2$ ,<br>limited only by the cooling beam [34]. In our scheme, the limited only by the cooling beam [\[34\]](#page-4-33). In our scheme, the trapping beam limits the cooling process, and since the mechanical frequency depends on detuning and power of the trapping beam, laser cooling becomes a bigger challenge. We find that ground state cooling can be achieved provided the cavity finesse is larger than 4000, detunings of trapping and cooling beams from cavity resonance are, respectively,  $\delta_1 \approx \kappa/2$  and  $\delta_2 = -\omega_m$  and the relative nower between the two beams differs by a factor of 10 to power between the two beams differs by a factor of 10 to avoid affecting the mirror stability. A plot of minimum mean phonon number at the optimal detunings is shown in Fig. [3\(b\)](#page-2-0) as a function of cavity finesse.

Both laser intensity fluctuations and background collisions are mechanisms of damping that lower the effective mechanical  $Q$  of the mirror. Assuming we are in the regime of negligible laser noise, the coupling to a thermal reservoir increases the attainable mean phonon number by  $\langle N \rangle = (\gamma_{rp} \langle n \rangle_{\text{min}} + \gamma_m \langle n_{\text{th}} \rangle) / (\gamma_{rp} + \gamma_m)$ . A high finesse cavity at low vacuum pressures offers a very low mechanical dissipation  $\gamma_m$  and minimum phonon number  $\langle n \rangle_{\text{min}}$ well below one; hence, the ground state of the mirror can, in principle, be reached by cavity cooling.

Applications.—The proposed optomechanical system can provide ultra-low-dissipation mechanical vibration and large optomechanical coupling suitable for various purposes. We briefly consider two possible applications: gravitational measurements and squeezing.

The optical spring means that any change in weight of the mirror will linearly alter the intracavity and output optical power. The gravitational acceleration g will therefore be linear with the cavity output power. Assuming a shot-noise limited laser and impedance-matched cavities, we find  $\delta g/g = \delta P/P = 1/\sqrt{n_{ph}}$  where  $n_{ph}$  is the mean<br>photon number. Detecting 100 mW of newer thus gives a photon number. Detecting 100 mW of power thus gives a precision around  $10^{-11}$  for an integration time of 100 s. This level of performance complements, and could present sensitivity improvements to, modern atom interferometry techniques [[41](#page-4-34)]. The trapping time is subject to laser noise and seismic vibrations that are considered to be minimal in this estimation and more realistic estimation requires detailed analysis that is beyond the scope of this Letter.

The highly isolated mechanical system proposed here can be strongly coupled to optical fields of three cavities where the measurement of the mirror position can be performed with high accuracy and it can be used for sensing and metrology applications. Because of the nonlinear dependence of the cavity resonance frequency on the mirror position it is possible to obtain quadrature squeezing at very low frequencies [\[14,](#page-4-9)[42\]](#page-4-35) that is desirable for gravitational wave detectors such as LIGO. Furthermore, strong optomechanical interactions in ultralow loss environment have been proven to facilitate testing the theory of semiclassical gravity [[43\]](#page-4-36).

In conclusion, we devised an optomechanical system in which a cavity mirror can be suspended and be maximally decoupled from the environment on three optical springs. The proposed system suppresses the scattering-induced heating and clamping dissipation and is an ultimate example of optical levitation. We showed that such a system provides an isolated macroscopic oscillator with a very high mechanical quality factor. We also investigated the possibility of reaching the quantum regime by means of laser cooling.
