(Received 3 June 2013; published 27 November 2013)

Filamentation due to the growth of a Weibel-type instability was observed in the interaction of a pair of counterstreaming, ablatively driven plasma flows, in a supersonic, collisionless regime relevant to astrophysical collisionless shocks. The flows were created by irradiating a pair of opposing plastic (CH) foils with 1.8 kJ, 2-ns laser pulses on the OMEGA EP Laser System. Ultrafast laser-driven proton radiography was used to image the Weibel-generated electromagnetic fields. The experimental observations are in good agreement with the analytical theory of the Weibel instability and with particle-in-cell simulations.

DOI: [10.1103/PhysRevLett.111.225002](http://dx.doi.org/10.1103/PhysRevLett.111.225002) PACS numbers: 52.72.+v, 52.35.Qz, 52.50.Jm, 95.30.Qd

Astrophysical shock waves play diverse roles, including energizing cosmic rays in the blast waves of astrophysical explosions [[1\]](#page-4-0), and generating primordial magnetic fields during the formation of galaxies and clusters [\[2\]](#page-4-1). These shocks are typically collisionless, and require collective electromagnetic fields [\[3](#page-4-2)], as Coulomb collisions alone are too weak to sustain shocks in high-temperature astrophysical plasmas. The class of Weibel-type instabilities [[4](#page-4-3)[–6\]](#page-4-4) (including the classical Weibel and current-filamentation instabilities) is one such collective mechanism that has been proposed to generate a turbulent magnetic field in the shock front and thereby mediate shock formation in cosmological shocks [[7](#page-4-5)] and blast wave shocks in gamma ray bursts  $[8-10]$  $[8-10]$  $[8-10]$  and supernova remnants  $[11]$ . These instabilities generate magnetic field de novo by tapping into nonequilibrium features in the electron and ion distributions functions. The classical form of the Weibel instability is driven by temperature anisotropy [\[4](#page-4-3)], but counterstreaming ion beams, as occur in the present context, provide an equivalent drive mechanism [\[6](#page-4-4)]. A related current filamentation instability of relativistic electron beams [\[12\]](#page-4-9) has also previously been observed in experiments driven by ultraintense lasers [\[13\]](#page-4-10).

We report experimental identification of an ion-driven Weibel-type instability generated in the interaction of two counterstreaming laser-produced plasma plumes. A pair of opposing plastic (CH) targets was irradiated by kilojouleclass laser pulses on the OMEGA EP Laser System, driving a pair of ablative flows toward the collision region at the midplane between the two foils. Due to the long mean free path between ions in opposing streams, the streams interpenetrate, establishing supersonic counterstreaming conditions in the ion populations, while the electrons form a single thermalized cloud. Meanwhile, the plasma density is also sufficient so that the the ion skin depth  $d_i =$  $(m_i/\mu_0 n e^2)^{1/2}$  is much smaller than the system size L.

These conditions allow the growth of an ion-driven Weibel instability, for which  $d_i$  is the characteristic wavelength [\[14–](#page-4-11)[16\]](#page-4-12). The Weibel-generated electromagnetic fields were observed with an ultrafast proton radiography technique [\[17\]](#page-4-13), and identified through good agreement with analytic theory [\[6](#page-4-4)] and particle-in-cell simulations, discussed below.

Figure [1](#page-0-0) shows a schematic of the experiments. A pair of opposing CH targets, separated by  $2L = 4.5$  mm, were each irradiated with 1.8 kJ, 2-ns laser pulse at a wavelength of 0.351  $\mu$ m. The laser pulses irradiated the targets at a highly oblique angle of incidence ( $\theta \approx 74^{\circ}$ ), leading to highly elliptical focal spots ( $e \approx 3.5$ ). The beam foci had a minor diameter of 900  $\mu$ m, and used distributed phaseplate beam smoothing, for on-target laser intensities near  $5 \times 10^{13}$  W/cm<sup>2</sup>. The laser setup was similar to the recent interacting plume experiments of Kugland *et al.* [\[18\]](#page-4-14), in which large-scale ''self-organized'' plasma structures were observed, except for smaller separation of the targets and

<span id="page-0-0"></span>

FIG. 1 (color). Experimental setup: plasma plumes are ablated from a pair of CH targets, separated by  $2L = 4.5$  mm, which collide and interact in the midplane. The electromagnetic fields formed due to instabilities in the interaction were radiographed with a laser-driven proton beam and imaged onto radiochromic film (RCF).

the use of broader laser foci and distributed phase plate beam smoothing, which may limit the density and decrease the magnitude of self-generated magnetic fields.

The electromagnetic fields formed in the interaction region were probed using an ultrafast diagnostic proton beam [[17\]](#page-4-13), generated with a third, high-intensity laser pulse (1.053  $\mu$ m, 800J, 10 ps) focused to  $>10^{18}$  W/cm<sup>2</sup>, irradiating a thin Cu disk 8 mm from the interaction region with a focal spot of about 25  $\mu$ m. This created a uniform and laminar point source of protons, with a distribution of energies of order 10 MeV via the target-normal sheath acceleration mechanism [[19](#page-4-15)]. A Ta shield prevented the ablated plasmas from interfering with the proton beam formation. The protons were detected with a stack of radiochromic film 80 mm from the interaction region, for a geometrical magnification of 11, with proton energies resolved in the film stack by their varying Bragg peaks. Figure [2](#page-1-0) shows the development of the instability in a sequence of radiographic images, taken over multiple experimental shots by varying the timing of the proton beam with respect to the main driver lasers. The two ablator targets are visible at the left and right of the images. The sequence of proton images reflects the electromagnetic structures formed in the plasma as the two plasma plumes interpenetrate.

The first image, at  $t = 3.8$  ns relative to the start of the driver pulse, shows a prominent and sharp " $X$ "-like structure at the midplane, with the protons deflected into pairs of thin lines, reminiscent of the caustic proton structures observed in experiments in a similar laser-energy regime with larger initial target separation [[18](#page-4-14)[,20](#page-4-16)]. However, for

the present discussion, we focus on the filamentary instability visible above the  $X$  structure. In the inset, a 1D cut shows a quasiperiodic variation in proton fluence, which is still relatively weak at this time, suggesting that this frame catches the linear growth of the instability just as it becomes measurable with the proton diagnostic. The instability has a wavelength of about  $100-120 \mu$ m transverse to the counterstreaming flows, and only a single wavelength or eigenmodelike structure parallel to the flows, over a width of about 500  $\mu$ m. The second image at  $t = 4.8$  ns shows substantial growth of the instability, with much larger variation in proton fluence, and with wavelengths transverse to the counterstreaming flows of order 120–150  $\mu$ m. The proton fluctuations still retain a filamentary character with longer correlation lengths parallel to the flows; however, the growth of multiple modes has replaced the clean single-eigenmode structure from 3.8 ns. The third image, at  $t = 5.8$  ns, shows the nonlinear evolution of the instability. There remains a primary ''spine'' of instability along the midplane. However, the typical wavelengths are even longer in the vertical direction, and the ratio of wavelengths parallel and perpendicular to the flows is closer to unity. This can reflect the nonlinear evolution of the instability, including coalescence of filaments or the dilation of filaments frozen into the outflows of plasma from the stagnation point at the midplane.

Radiation-hydrodynamics simulations with the DRACO code [[21](#page-4-17),[22](#page-4-18)] provide baseline predictions for interpreting the observations. The simulations show quasi-isothermal plasma ablation [\[23\]](#page-4-19) with initial electron temperatures  $T_e$ near 800 eV driving a supersonic ablation stream flowing

<span id="page-1-0"></span>

FIG. 2 (color). Radiochromic film images of the development of a striated instability at the midplane at 3.8, 4.8, and 5.8 ns relative to the start of the main driver laser pulse. The film records fluence of protons with energy of order 5–10 MeV, with darker features reflecting greater proton fluence. The striated features are well reproduced on neighboring film in the stack, reflecting the strong focusing of the diagnostic proton beam [\[20\]](#page-4-16). The insets show 1D traces of proton intensity along the long axis of the regions denoted in the film, averaged over the short direction, from which a quadratic background proton variation was subtracted to focus on the fluctuations. Typical filament wavelengths of 100–150  $\mu$ m at 3.8 and 4.8 ns expand to wavelengths near 250  $\mu$ m at 5.8 ns. The distances on the axes are those in the nominal object plane, which is perpendicular to the axis of the proton beam and the targets, and which goes through the center of the UV drive laser foci. The image has been sharpened in postprocessing to emphasize the striations. (Raw images are available in the Supplemental Material [[28](#page-4-20)]).

from each target with  $V \approx C_s + x/t$ , and density  $n \approx$  $n_{ab} \exp(-\alpha x/C_s t)$ . Here  $C_s \approx 2 \times 10^5$  m/s is the sound speed,  $x$  measures the distance from the ablation surface, and t is time. The ablation density  $n_{ab}$  of  $7 \times 10^{26}$  m<sup>-3</sup> is reduced compared to the critical density owing to the highly oblique laser incidence, and  $\alpha$  is a factor of order 1. The conditions at the midplane during instability growth are estimated by superposition of single-plume DRACO simulations; for example, at  $t = 3.8$  ns, the electron density (summed over both plumes) is  $2 \times 10^{25}$  m<sup>-3</sup>, and the electron temperature is 250 eV. The ion distribution function consists of two counterstreaming beam components with flow speeds  $\pm V$  near  $8 \times 10^5$  m/s, with single-stream ion temperatures near 150 eV. Under such conditions the ion-ion interplume interaction is quasicollisionless, with the  $C^{6+}$ - $C^{6+}$  mean free path between the opposing streams of order 10 cm, and the  $C^{6+}$ -electron mean free path at least 4 mm (and likely longer if the electrons are heated in the interaction region  $[24]$  $[24]$  $[24]$ ). Meanwhile, the electron collision frequency is faster than the dynamics we consider; therefore, the electrons form a single thermalized population.

These collisionless, counterstreaming conditions at the midplane are requisite conditions to drive the Weibel instability, and the observations bear many expected qualitative features of this instability, including localization to the overlap region and formation of elongated filaments parallel to the ablation flows. We have obtained quantitative agreement with the local electromagnetic dispersion relation for the ion-driven Weibel instability [\[6](#page-4-4)], which includes counterstreaming ions but a single collisionally thermalized electron population. The dispersion relation is solved directly for the maximum growth rate  $\gamma_{\text{max}}$  and fastest-growing wavelength  $\lambda_{\text{max}}$  versus the electron and ion temperature (shown in Fig. [3\)](#page-2-0), and shows robust instability growth over a wide range of temperatures and possible fractionation effects in the colliding plasmas. Furthermore, when the growth rate is normalized to the counterstreaming speed V and the fastest-growing wavelength for each ion temperature, as in Fig.  $3(a)$ , the results are remarkably constant over orders of magnitude variation in ion temperature, demonstrating that  $V/\lambda$  is the dominant scaling. Experimentally, this is important, as recent experiments have observed complex heating dynamics of both electrons and ions in similar counterstreaming conditions [\[24](#page-4-21)[,25\]](#page-4-22). Instead, this dominant scaling enables straightforward comparison of observations and the linear theory: the wavelengths are measured in the radiography, and the interaction speed  $V \approx C_s + L/t$  is well constrained due to the simple nature of the ablative flow. For example, for  $t =$ 3.8 ns, V is estimated as  $8 \times 10^5$  m/s, and DRACO predicts a single-stream ion temperature of 150 eV. Accounting for possible ion heating leads us to consider a range of  $T_i/m_pV^2$  from 0.01 to 0.1. In this  $T_i$  range, and considering the heated electron curve (dashed curves),

<span id="page-2-0"></span>

<span id="page-2-1"></span>FIG. 3 (color). (a) Growth rate of Weibel instability and (b) wavelength of fastest growing mode versus ion temperature. Specifically, we solve the ion-pinch dispersion relation of Davidson *et al.* [[6](#page-4-4)], using zero electron anisotropy due to the electron collisionality regime of the experiments. The growth rate is normalized to the counterstreaming speed V and wavelength of maximum growth for each ion temperature. The blue curves are for a 60:40 H-C mixture close to the composition of the targets, and the red curves are for a 90:10 mixture reflecting fractionation. Solid curves are for  $T_e = T_i$ , and the dashed curves are for heated electrons with  $T_e = 0.25 m_p V^2$ . To compare wavelengths on an even footing, for both compositions the wavelengths are normalized to a nominal  $d_{iCH}$  calculated with the 60:40 H-C mixture:  $d_{i \text{CH}} \approx 1.29 (m_p / \mu_0 n_e e^2)^{1/2}$ .

 $\gamma \approx 0.5V/\lambda$ . Assuming that the observed wavelengths (near 150  $\mu$ m) are close to the fastest growing modes, the growth rate is then estimated at  $2-3 \times 10^9$  s<sup>-1</sup>, which is consistent with the rapid appearance of the filaments on the 1 ns period separating adjacent frames.

The observed wavelengths are also in reasonable agreement with Weibel-instability theory for DRACO-predicted plasma densities at the midplane. Following Fig. [3\(b\)](#page-2-1),  $\lambda_{\text{max}}/d_{i\text{CH}} \approx 1$  for the expected range of ion temperature, implying  $d_{iCH} \approx 150 \mu \text{m}$ . To compare, DRACO simulations find densities near  $2 \times 10^{25}$  m<sup>-3</sup> at the midplane for  $t = 3.8$  ns, corresponding to  $d_{iCH} \approx 65 \mu$ m. This is in reasonable agreement, and indicates that the observed filaments are certainly on the ion scale. [In contrast, they are much too large to be explained by the beam-driven electrostatic instability, also present in the counterstreaming flow geometry [\[26](#page-4-23)], but which has characteristic wavelengths on the much smaller electron scale  $d_e$  =  $(m_e/\mu_0 n_e e^2)^{1/2}$ .] The remaining factor of 2–3 disagreement in wavelength may be explained by a combination of factors: (i) the possibility that DRACO is overpredicting density at the midplane, possibly related to how the true elliptical laser focus is converted to a cylindrically symmetric profile required by DRACO, (ii) limitations of the local dispersion relation, which excludes nonlocal effects, and (iii) the possibility that nonlinear filament merging has already begun [[10](#page-4-7),[27](#page-4-24)].

Finally, the observations are in agreement with particlein-cell simulations. The ablation flow geometry of the experiment is generated by seeding plasma to small volumes at the left and right boundaries of the computational domain, which is initially in vacuum. Figure [4](#page-3-0) shows the evolution of the plasma density and the development of magnetic filaments at the midplane due to the Weibel instability as the two flows interpenetrate. (The setup of the simulations is discussed in detail in the figure caption.) The Weibel-generated fields grow and saturate on comparable time scales to the experiment, measured in units of the dynamic time  $L/C_s \approx 11$  ns in experiment), where L is the target half separation and  $C_s$  is the sound speed. The growth rates and characteristic wavelength of the modes at the midplane are measured directly in the simulations and are in reasonable agreement with the same iondriven linear Weibel theory [\[6](#page-4-4)]. The simulations predict peak Weibel-generated fields of order 20 T, using the DRACO-predicted ablation parameters, giving a B field energy approximately 1% of equipartition with the flow energy (cf. Ref. [[11](#page-4-8)]). This is in reasonable agreement with the proton caustic formation by magnetic deflection [[20\]](#page-4-16), which requires  $\nabla_{\perp} \int \mathbf{B} \times d\ell \sim 60 \text{ T}$  for typical proton energies and the experimental proton magnification factors. Here the line integral is along the proton trajectories and the gradient is taken in the object plane. This value can be interpreted as an upper bound from caustic lensing ''by one filament.'' For cumulative lensing by multiple filaments, the required magnitude per filament is correspondingly lower. Finally, an important point is that in this 2D simulation, the filaments are the transverse B component (out of the page). Interestingly, this component does not scatter the diagnostic proton beam, at least to lowest order. However, in reality the magnetic turbulence will consist of a 3D honeycomb of filaments [\[27\]](#page-4-24) with additional magnetic field components (required by  $\nabla \cdot \mathbf{B} = 0$ ), which would produce an observable perturbation to the diagnostic beam.

This work has identified plasma stream filamentation due to a Weibel-type instability between collisionless counterstreaming laser-produced plasma plumes, and simultaneously modeled its growth and saturation with massively parallel particle-in-cell simulation. This instability has been proposed to be a necessary ingredient in forming shocks in otherwise collisionless unmagnetized plasmas. These results suggest that future experiments at greater system size and at greater energy may be able to observe and study fully formed Weibel-mediated collisionless shocks and study their consequences for particle energization.

The authors thank the OMEGA EP team for conducting the experiments. The particle-in-cell simulations were conducted on the Jaguar and Titan supercomputers through the Innovative and Novel Computational Impact on Theory

<span id="page-3-0"></span>

FIG. 4 (color). Particle-in-cell (PIC) simulation of growth of Weibel filaments between counterstreaming ablation flows. Top: evolution of the plasma density. Bottom: development of transverse magnetic filaments from the Weibel instability. To generate the counterstreaming ablation-flow geometry, plasma is added dynamically to small volumes at the left and right boundaries for time  $t = [0, t_{\text{laser}}]$ . This sets up a pair of flows with ablationlike profiles for density  $[n \approx n_{ab} \exp(-\Delta x / C_s t)]$  and velocity  $(V \approx C_s + t_s)$  $\Delta x/t$ , where  $\Delta x$  is the distance from the boundaries, C<sub>s</sub> is the sound speed evaluated using the source temperature, and  $n_{ab}$  is the peak density reached in the source region. The simulation uses two species, carbon ( $Z = 6$ ) and electrons, with heavy electrons ( $Zm_e/m_c$ 1/100), compared to the physical mass ratio, for computational reasons. The domain is  $[-L, L]$  along x and  $[0, 2L/3]$  along the transverse direction, which is included to allow multiple wavelengths of the Weibel instability to grow. We approximately match the ion-scale dimensionless parameters  $L/d_{i,ab} \sim 180$  (experiment) versus 130 (simulation) and  $t_{\text{laser}}C_{s0}/L \sim 0.17$  (experiment) versus 0.21 (simulation).  $(d_{i,ab}$  is the ion-skin depth calculated using the ablation density.) Interparticle collisions are modeled using a Monte Carlo binary collision operator, with the collisionality chosen so that  $v_{ei}/\gamma_{weib} \sim 10$  during instability growth, as estimated in the experiment. The simulations were conducted with the massively-parallel, explicit particle-in-cell code PSC [\[29](#page-4-25)], using approximately  $5.7 \times 10^9$  computational particles.
