(Received 2 February 2015; published 11 June 2015)

In a quasi-two-dimensional electron system with nonzero layer thickness, a parallel magnetic field can couple to the out-of-plane electron motion and lead to a severe distortion and eventual splitting of the Fermi contour. Here we directly and quantitatively probe this evolution through commensurability and Shubnikov–de Haas measurements on electrons confined to a 40-nm-wide GaAs (001) quantum well. We are able to observe the Fermi contour splitting phenomenon, in good agreement with the results of semiclassical calculations. Experimentally, we also observe intriguing features, suggesting magnetic-breakdown-type behavior when the Fermi contour splits.

In a strictly two-dimensional electron system (2DES) with zero layer thickness, the electron in-plane motion is unaffected by a parallel magnetic field  $(B_{\parallel})$ . However, for a quasi-2DES, such as electrons in a quantum well (QW) with finite width,  $B_{\parallel}$  can couple to electrons' out-of-plane motion, thus also affecting their in-plane motion. This can have profound consequences. For example, the Fermi contour, which is circular in an isotropic system such as the 2DES in GaAs QWs, becomes severely distorted by  $B_{\parallel}$ and could even split into two tear-drop shaped contours if  $B_{\parallel}$  is sufficiently strong (Fig. 1).  $B_{\parallel}$  also causes spin polarization, leading to the formation of two distinct Fermi contours with different enclosed areas for different spins. Therefore, the spin-degenerate Fermi contour at B = 0 could split into two pairs of smaller contours in the presence of a large  $B_{\parallel}$  (Fig. 1). Since the shape of the Fermi contour, when rotated by 90°, reflects that of the cyclotron orbit in real space [1], its evolution as a function of  $B_{\parallel}$  corresponds to the evolution of the electron trajectory. Understanding this  $B_{\parallel}$ -induced Fermi contour splitting is of fundamental importance, especially for spintronic devices where the application of  $B_{\parallel}$  is often used for spin polarization [2,3].

Several transport studies on 2DESs, confined to coupled double- [4–9] and triple-QW systems [10], have previously explored the Fermi contour splitting. In these studies, features such as kinks in the  $B_{\parallel}$ -induced magnetoresistance and interlayer tunneling were associated with the splitting. Electrons in very wide single QWs, which are essentially bilayer systems, also produced similar results [11]. Compared to the earlier works, our study here incorporates the following novelties: (1) The 2DES is confined to a single QW with a *single-layer-like* charge distribution at  $B_{\parallel} = 0$  [see the inset of Fig. 1(a)]. (2) We probe the splitting of the Fermi contour for both *spin* species via Shubnikov–de Haas (SdH) oscillations. (3) We use measurements of commensurability oscillations (COs), also

known as Weiss oscillations [12], to directly map out the Fermi contour and capture its distortion and the eventual splitting.

Our sample, grown via molecular beam epitaxy, is a 40-nm-wide GaAs (001) QW which is located 190 nm under the surface. The QW is flanked on each side by 95-nm-thick  $Al_{0.24}Ga_{0.76}As$  spacer layers and Si  $\delta$ -doped layers. The 2DES density is  $n = 1.75 \times 10^{11} \text{ cm}^{-2}$ , and the mobility is  $\sim 20 \times 10^6$  cm<sup>2</sup>/Vs. We fabricated a straininducing superlattice with a period a = 400 nm on the surface of our sample, an L-shaped Hall bar [Fig. 2(a)]. The superlattice, made of negative electron-beam resist, modulates the potential through the piezoelectric effect in GaAs [13–17]. For  $B_{\parallel}$ -dependent measurements, we first apply a large B field in the plane along [110]. The sample, mounted on a single-axis tilting stage, is then slowly rotated around  $[\bar{1}10]$  using a computer-controlled, brushless dc motor to introduce a small component of the field perpendicular to the 2D plane. This  $B_{\perp}$  induces SdH oscillations in the unpatterned reference and COs in the modulated regions of the Hall bar. (Note that  $B_{\parallel} \cong B$ because  $B_{\perp} \ll B$ .) We pass current along the L-shaped Hall bar and measure the longitudinal resistances simultaneously for both arms.  $B_{\perp}$  is extracted from a linear fit of the Hall resistance measured in the reference region. All measurements are carried out at 300 mK.

Figures 1(a)–1(e) highlight the key points of our study. The Fermi contours are derived from calculations based on an 8 × 8 Kane Hamiltonian with no adjustable parameters [18]. We include  $B_{\parallel} = (B_x, B_y, 0)$  via the vector potential  $A(z) = (zB_y, -zB_x, 0)$  so that the in-plane canonical momentum  $\mathbf{k} = (k_x, k_y, 0)$  remains a good quantum number. The occupied states enclosed by the Fermi contours define the charge density from which the Hartree potential is derived self-consistently. As seen in Fig. 1(a), the Fermi contours of the two spin subbands, which are identical for

FIG. 1 (color online). (a)–(e) Calculated Fermi contours for a 2DES with density  $n = 1.75 \times 10^{11}$  cm<sup>-2</sup> confined to a 40-nm-wide GaAs QW.  $B_{\parallel}$  is applied along [110]. Insets show the corresponding charge distributions in light blue. Inset of (e) also shows the charge distribution from the  $k[\bar{1}10] > 0$  (the shaded pink region) and  $k[\bar{1}10] < 0$  (the shaded yellow region) states.

 $B_{\parallel} = 0$ , start out circular [19]. As  $B_{\parallel}$  increases, the 2DES becomes progressively more spin polarized, thus two distinct spin Fermi contours are formed. The application of  $B_{\parallel}$  along [110] also elongates and splits the contours in the [ $\bar{1}10$ ] direction. Figures 1(c) and 1(d) illustrate the splitting of the minority and majority spin contours, respectively. The split contours separate even further along [ $\bar{1}10$ ] under stronger  $B_{\parallel}$  [Fig. 1(e)] The insets of Figs. 1(a)–1(e) show how the charge distribution along the confinement direction gradually evolves from a single-layer into a bilayer, with each of the "layers" corresponding to one part of the split Fermi contour [see the Fig. 1(e) inset].

PRL 114, 236404 (2015)

As an indication of Fermi contour splitting, we first present the  $B_{\parallel}$ -magnetoresistance trace from the reference region of the Hall bar [Fig. 2(b)]. The trace demonstrates nonmonotonic transport behavior. In particular, there are two pronounced kinks at  $\cong 11$  T and  $\cong 14$  T, marked by red and green circles, respectively. The positions of these kinks agree well with the expected splitting of the minority and majority spin contours [see Figs. 1(c) and 1(d)]. A kink in the  $B_{\parallel}$  magnetoresistance has previously been associated with the splitting of the Fermi contour [9]. Here, we observe two kinks, suggesting a spin-dependent splitting of Fermi contours.

We further investigate the splitting via SdH oscillations which directly probe the area enclosed by the Fermi contour. We expect that the splitting would be reflected as a jump in the SdH frequency. Figure 3(a) shows the SdH oscillations at different  $B_{\parallel}$ 's, while the corresponding Fourier transforms (FTs) are shown in Fig. 3(b). For  $B_{\parallel} = 0$  T, we observe two peaks, the stronger of which  $(f_{\text{SdH}}^0 = 3.56 \text{ T})$  is for the spin-unresolved SdH oscillations (marked by a dotted vertical line). The weaker peak at 7.08 T is very close to the value of  $2f_{SdH}^0$  (marked by a solid vertical line) and corresponds to the spin-resolved oscillations [20]. Around  $B_{\parallel} = 9$  T, the spin-unresolved peak splits, with the lower frequency peak  $f^-$  (a red square) corresponding to the electron density of the minority-spin subband and the higher frequency peak  $f^+$  (a green square) to the majority-spin subband. Then, starting at  $B_{\parallel} \cong 11$  T, another low-frequency peak  $f_{1/2}^-$  (a red square) appears at approximately  $f^{-}/2$ , signaling the splitting of the minority spin contour. The  $f_{1/2}^-$  peak remains dominant between  $B_{\parallel} = 11.5$  and 13.5 T, where both  $f^+$  and  $f^-$  become very weak and essentially vanish. However, at  $B_{\parallel} \cong 14$  T, another peak  $f_{1/2}^+$  (a green square) appears to the right of  $f_{1/2}^-$  and becomes the dominant feature in the FT spectrum up to  $B_{\parallel} = 18$  T. The sum of  $f_{1/2}^-$  and  $f_{1/2}^+$  is close to  $f_{\text{SdH}}^0$ , implying that  $f_{1/2}^+$  originates from the split majority spin Fermi contour. We do not fully understand the origin of the weak peaks marked by open symbols in Fig. 3(b). They might stem from a magnetic breakdown between the split contours [21,22]; a similar phenomenon has been invoked to explain anomalous SdH frequencies seen in bilayer electron systems confined to double-QW samples in  $B_{\parallel}$  [8].

We summarize, in Fig. 3(c), the results of the Fermi contour calculations and the measured SdH frequencies (the red and green squares), normalized to  $f_{\text{SdH}}^0$ . The calculated frequencies for majority and minority spin contours, which are equal to the calculated Fermi contour areas multiplied by  $h/(2\pi^2 e)$ , halve at  $B_{\parallel}$  values that mark the splitting of the respective contours. These jumps in frequency reflect the fact that, for a small  $B_{\parallel}$ , the plotted curves are based on the areas enclosed by the unbroken Fermi contours, whereas for a larger  $B_{\parallel}$ , they are based on the areas of each of the split contours. There is good overall agreement between the measured and calculated SdH

FIG. 2 (color online). (a) Sample schematics. The electronbeam resist grating covering the surface of each Hall bar arm is shown as blue stripes. Part of the [110] arm is left unpatterned as a reference region. (b)  $B_{\parallel}$ -induced magnetoresistance for  $R_{\rm ref}$ . A–E mark the  $B_{\parallel}$  values that correspond approximately to the calculations of Fig. 1.

FIG. 3 (color online). (a) SdH oscillations measured in the reference region of the Hall bar as  $B_{\parallel}$  increases; traces are shifted vertically for clarity. (b) FT spectra of the SdH oscillations. The dotted and solid black lines show the expected positions of the spin-unresolved and spin-resolved FT peaks at  $B_{\parallel} = 0$ , respectively. The FT signal to the left of the vertical lines indicated by  $\div 10$  and  $\div 50$  is affected by the Hamming window used in the Fourier analysis and is shown suppressed. (c) Summary of the FT peak positions normalized to  $f_{\text{SdH}}^o$ , the frequency at  $B_{\parallel} = 0$ . Closed squares represent the measured frequencies. The frequencies predicted by the calculations for the spin subbands are shown as green and red lines. A–E mark the  $B_{\parallel}$  values from Fig. 1 calculations.

frequencies [23]. This suggests that SdH oscillations indeed show the spin-dependent splitting of Fermi contours, corroborating our interpretation of the two kinks observed in the  $B_{\parallel}$  magnetoresistance [Fig. 2(a)].

Having established the Fermi contour splitting through  $B_{\parallel}$  magnetoresistance and SdH oscillations, we now turn to CO data measured in the modulated regions of the Hall bar. The magnetoresistance trace of Fig. 4(a), taken as a function of purely  $B_{\perp}$ , is representative of such COs exhibiting pronounced minima at the electrostatic commensurability condition  $2R_C/a = i - 1/4$  [12,24–29],

FIG. 4 (color online). (a) COs along [110] from the patterned region. Vertical lines mark the expected positions of the COs' resistance minima. The corresponding trace from the unpatterned reference region clearly shows no COs. (b),(c) COs from the patterned regions of the L-shaped Hall bar along [110] and [110] for different values of  $B_{\parallel}$ . In order to do Fourier analysis, we extract the oscillatory part of these traces as a function of  $1/B_{\perp}$  by subtracting the background resistance. Examples of this process are shown as top three traces in (b). Traces are shifted vertically for clarity. (d),(e) Normalized FT spectra of the CO data shown in (a) and (b), respectively. The vertical dotted lines mark  $f_{CO}^0$  (see text).

FIG. 5 (color online). Summary of the Fermi wave vectors  $(k_F)$  deduced from the positions of the CO FT spectra for the two Hall bar arms. Blue and red symbols represent the experimental data for  $k_F \perp B_{\parallel}$  and  $k_F \parallel B_{\parallel}$ , respectively. A–E mark the  $B_{\parallel}$  values from the calculations of Fig. 1.

where i = 1, 2, 3...,  $R_C = k_F/eB_{\perp}$  is the real-space cyclotron radius, and *a* is the period of the potential modulation ( $k_F$  is the Fermi wave vector perpendicular to the current direction). The frequency of COs,  $f_{\rm CO} = 2\hbar k_F/ea$ , directly measures  $k_F$ . Note that the very high mobility of our sample leads to a large number of oscillations, up to  $i \ge 12$ .

The magnetoresistance data from the [110] and [110] Hall bar arms are shown in Figs. 4(b) and 4(c). In each figure, the bottom traces, taken in the absence of  $B_{\parallel}$ , exhibit high-quality COs. As  $B_{\parallel}$  is increased, there is an obvious change in the periodicity of COs which is better seen in the FT spectra of Figs. 4(d) and 4(e). The bottom FT spectrum from each of these figures exhibits a single peak whose position ( $\approx 0.35$  T) is consistent with the commensurability frequency  $f_{CO}^0 = 2\hbar k_F/ea = 0.35 \text{ T}$  (the dotted line) expected for a circular, spin-degenerate Fermi contour with  $k_F = \sqrt{2\pi n}$ . With increasing  $B_{\parallel}$ , this peak f moves to higher frequencies in the FTs for the [110] Hall bar arm [Fig. 4(d)] and to lower frequencies in the  $[\bar{1}10]$  arm [Fig. 4(e)], suggesting that the Fermi contour is getting elongated. However, at  $B_{\parallel} \cong 12.5$  T, a new peak  $f_{1/2}$ emerges at approximately f/2 in Fig. 4(d). This indicates that the elongated contour has split into two smaller ones. As  $B_{\parallel}$  is increased further,  $f_{1/2}$  develops into the strongest feature of the FT spectra in Fig. 4(d). In contrast, f becomes progressively less pronounced and vanishes at  $B_{\parallel} \cong 16$  T.

Figure 5 summarizes the values of  $k_F$  extracted from the FT frequencies and also from the calculated Fermi contours for which we take the extrema along [110] and [ $\overline{1}10$ ] (see the left inset) and plot them with bold red and blue lines, respectively. However, after the splitting,  $k_F$  along [ $\overline{1}10$ ], defined as shown in Fig. 5's right inset (the thin blue line

with an arrow), is represented by a thin blue line. We also plot half the length of the major axis along [ $\bar{1}10$ ] of the split contour (see the right inset) by a bold blue line. Qualitatively, the measured values of  $k_F$  show good agreement with the calculations, suggesting that the peak  $f_{1/2}$ comes from the split Fermi contour. Calculations (see Fig. 1) also show that the extreme sizes of the contours for the two spin species always remain very similar. This explains why, unlike the SdH oscillations data, COs do not resolve the two spin Fermi contours [17]. Another key point of Fig. 5 is that the elongation of the Fermi contour deduced from the CO data is smaller than what the calculations predict. A similar discrepancy was previously observed in other 2D electron and hole systems [15,17,30].

Another noteworthy feature of the CO data is that, even after the Fermi contour splits at  $B_{\parallel} \cong 12$  T, we appear to still follow f up to  $B_{\parallel} \cong 16$  T [marked by solid blue circles in Figs. 4(d) and 5]. To explain this, we propose a magnetic breakdown-like scenario [21,22] where, even though the Fermi contour is split into two pieces, we still observe COs because a small portion of electrons jump between the split contours and complete the elongated orbit. In this context, magnetic breakdown in k space implies that, in real space, there is tunneling between layers which are separated because of a strong  $B_{\parallel}$  [see the Fig. 1(e) inset].
