(Received 15 April 2015; published 14 July 2015)

The first absolute experimental determinations of the differential cross sections for the formation of ground-state positronium are presented for He, Ar, H₂, and CO₂ near 0°. Results are compared with available theories. The ratio of the differential and integrated cross sections for the targets exposes the higher propensity for forward emission of positronium formed from He and H₂.

The formation of positronium (Ps, the bound state of an electron and a positron) is an important channel in the scattering of positrons from atoms and molecules, e.g., [1–3], accounting for up to 50% of the total cross section, with experimental and theoretical investigations of its integrated formation cross sections available for a wide range of atoms and simple molecules, e.g., Refs. [3–5]. Recent experimental studies also include its formation in an excited state [6] or accompanied by ionic excitation [7]. However, while theoretical predictions for the differential Ps formation cross section ($dQ_{\text{Ps}}/d\Omega$) are available for atomic [8–16] and molecular [17,18] hydrogen, the noble gases [9,16,19–29], and the alkali metals [30–34], experimental data remain scarce. Indeed, available measurements are confined to H₂ [35], Ar, and Kr [36,37] and, due to unknown positron and Ps detection efficiencies (ϵ_d^+ and ϵ_d^{Ps} , respectively), these results are *relative* and susceptible to *energy-dependent* systematic errors.

In this communication, we present the first absolute experimental determinations of $dQ_{\text{Ps}}/d\Omega$ for He, Ar, H₂, and CO₂. The values are extracted from measurements of the production efficiency of the Ps beam at UCL and thus correspond to a small angle around 0°. An absolute scale has been assigned by using experimental values for the ratio $R_d = \epsilon_d^+/\epsilon_d^{\text{Ps}}$ [38,39], together with a recent finding that, although ϵ_d^+ and ϵ_d^{Ps} may individually vary significantly (e.g., due to different detector types, ages, and settings), R_d does not do so appreciably [40]. Where possible, the results are compared with theoretical determinations at zero degrees.

Details of the experimental arrangement employed at UCL for producing a beam of Ps atoms, together with a review of recent advances, may be found in Ref. [41]. In brief, the Ps beam is produced by charge-exchange of positrons (e^+) with a target gas (A), i.e., $e^+ + A \rightarrow \text{Ps} + A^+$, and detected downstream by a channel-electron multiplier (CEM or CEMA) in coincidence with one or more γ -ray detectors (e.g., CsI or NaI). The beam has been found to be composed predominantly of ground-state atoms [42,43].

Depending on the relative spin orientation of its constituents, ground-state Ps may be formed in an ortho-(3S_1) or para-(1S_0) state. The two are characterized by lifetimes differing by 3 orders of magnitude (142 ns and 125 ps, respectively) and different annihilation modes (dominantly 3- γ and 2- γ , respectively). Only ortho-Ps reaches the detection region.

In order to determine $dQ_{\text{Ps}}/d\Omega$ (a measure of the probability that Ps is emitted within a solid angle $d\Omega = 2\pi \sin\theta d\theta$), we have measured the number of Ps atoms ($\epsilon_d^{\text{Ps}} N_{\Delta\Omega}^{\text{Ps}}$) detected in a small solid angle ($\Delta\Omega$) per measured incident positrons ($\epsilon_d^+ N_+$). These here define the measured Ps beam production efficiency (ϵ_{Ps}^m) according to

$$\epsilon_{\text{Ps}}^m = \frac{\epsilon_d^{\text{Ps}} N_{\Delta\Omega}^{\text{Ps}}}{\epsilon_d^+ N_+} = \frac{\epsilon_{\text{Ps}}}{R_d} e^{-t/\tau_{\text{Ps}}}, \quad (1)$$

where τ_{Ps} is the lifetime of ortho-Ps, t its flight time to the detector and ϵ_{Ps} the “true” Ps beam production efficiency. In Eq. (1), ϵ_{Ps}^m may be seen to depend on the (energy-dependent) ratio of the positron to positronium detection efficiencies R_d also determined by our group [38–40].

By studying the variation of ϵ_{Ps} with gas pressure, optimum beam operating conditions may be determined for a given target and Ps energy [39,40,44,45]. An example is shown in Fig. 1 for production of 20 eV Ps from CO₂. Here ϵ_{Ps} may be seen to increase and then decrease with increasing pressure. This variation may be expressed as

$$\epsilon_{\text{Ps}} = [1 - \exp(-\rho L_+ Q_T^+)] \left(\frac{2\pi}{Q_T^+} \int_0^{\theta'} \frac{dQ_{\text{Ps}}}{d\Omega} \sin\theta d\theta \right) \times \exp(-\rho L_{\text{Ps}} Q_T^{\text{Ps}}), \quad (2)$$

where the first term in brackets corresponds to the total fraction of positrons scattered in a gas region of number density ρ and length L_+ , the second to the probability that Ps will be formed within a small pencil angle θ' , and the third term to the transmission probability of Ps through the gas region of length L_{Ps} , Q_T^+ and Q_T^{Ps} being the positron-gas and Ps-gas total cross sections, respectively. If the differential cross section does not vary too rapidly over the small

FIG. 1. The Ps beam production efficiency (bullet) of CO₂ at a Ps energy of 20 eV. The corresponding prediction (triangle) using the weighted mean of $dQ_{\text{Ps}}/d\Omega$ (from the data in Fig. 2) is also shown.

range $0 \leq \theta \leq \theta'$ —namely, $(1.1\text{--}1.7)^\circ$ in this work—the second term may be approximated as

$$\frac{2\pi}{Q_T^+} \int_0^{\theta'} \frac{dQ_{\text{Ps}}}{d\Omega} \sin \theta d\theta \approx \left\langle \frac{dQ_{\text{Ps}}}{d\Omega} \right\rangle \frac{\Delta\Omega}{Q_T^+}, \quad (3)$$

where $\Delta\Omega$ is the (small) detection solid angle and $\langle dQ_{\text{Ps}}/d\Omega \rangle$ is the average value of $dQ_{\text{Ps}}/d\Omega$ over the range $(0 - \theta')$. Explicitly allowing for the fact that Ps may be formed anywhere along the gas cell of effective length L , we may express $L_{\text{Ps}} = L - \ell_+$, where ℓ_+ is the variable of integration in the following equation:

$$\begin{aligned} \epsilon_{\text{Ps}}^m &\approx \frac{3}{4} \frac{1}{R_d} \frac{1}{Q_T^+} \left\langle \frac{dQ_{\text{Ps}}}{d\Omega} \right\rangle \int_0^L \left[\exp(-\rho\ell_+ Q_T^+) \right. \\ &\times \exp(-\rho(L - \ell_+) Q_T^{\text{Ps}}) \left(\frac{\pi r^2}{(L - \ell_+ + d)^2} \right) \\ &\times \exp\left(-\frac{(L - \ell_+ + d)}{\tau_{\text{Ps}}} \sqrt{\frac{m}{E_{\text{Ps}}}}\right) \left. \right] \rho Q_T^+ d\ell_+, \quad (4) \end{aligned}$$

which allows for Ps formation and scattering along L , as well as for the corresponding variations in detection solid angle and in-flight Ps annihilation. Specifically, the factor of $3/4$ arises from the spin multiplicity of Ps; the third and fourth terms in the integral represent, respectively, the detection solid angle and in-flight survival probability: $L - \ell_+ + d$ being the Ps flight path to the detector of effective area πr^2 , E_{Ps} is the Ps kinetic energy and m the mass of the positron.

Approximating the integral in Eq. (4) with a summation over ℓ_+ in steps $\Delta\ell_+$ such that $\rho\Delta\ell_+ Q_T^+ \rightarrow 0$, and rearranging, we obtain for the absolute differential Ps formation cross section

$$\begin{aligned} \frac{dQ_{\text{Ps}}}{d\Omega} &\approx \left\langle \frac{dQ_{\text{Ps}}}{d\Omega} \right\rangle \approx \frac{4}{3} \frac{\epsilon_{\text{Ps}}^m R_d}{\rho \Delta\ell_+} \\ &\times \left\{ \sum_{\ell_+=0}^L \left[\exp(-\rho\ell_+ Q_T^+) \exp(-\rho(L - \ell_+) Q_T^{\text{Ps}}) \right. \right. \\ &\times \left(\frac{\pi r^2}{(L - \ell_+ + d)^2} \right) \\ &\times \left. \left. \exp\left(-\frac{(L - \ell_+ + d)}{\tau_{\text{Ps}}} \sqrt{\frac{m}{E_{\text{Ps}}}}\right) \right] \right\}^{-1}, \quad (5) \end{aligned}$$

where the approximation $dQ_{\text{Ps}}/d\Omega \approx \langle dQ_{\text{Ps}}/d\Omega \rangle$ has been made given the small acceptance angle used in this work. The values for the positron and Ps total cross sections have been taken from available literature, specifically from Refs. [46–49] and Refs. [50–52], respectively, interpolating when necessary. At 120 eV for He and Ar, where Ps data were not available, the cross sections were estimated by extrapolation, guided by the findings of Brawley *et al.* [50] on the similarity with equivelocity-electron results. The effective length of the gas cell (L) has been determined by measuring positron beam attenuations and normalizing to known cross section values across a number of targets [46–48,53–57].

Figure 2 displays the $dQ_{\text{Ps}}/d\Omega$ values obtained from ϵ_{Ps} (shown in Fig. 1) and Eq. (5). As expected, in Fig. 2, the cross section is seen to be (within errors) independent of pressure. However, in some cases where this was not found to be so, Q_T^+ and/or Q_T^{Ps} were varied in order to achieve pressure independence and to estimate the associated uncertainty on $dQ_{\text{Ps}}/d\Omega$ ($\leq 10\%$ in all cases, except for CO₂ at 139 eV where $\leq 18\%$ applies). An additional systematic uncertainty arises from that in R_d , estimated to be $+8\%$ and $-(20\text{--}30)\%$ [38]. At each energy, the absolute differential Ps formation cross section has been computed as the weighted mean of the results across the pressure range if within errors, else the mean and standard error are reported. As a check of self-consistency, the variation of ϵ_{Ps} predicted by this weighted mean is also shown in Fig. 1.

FIG. 2. Example of the absolute differential cross section for Ps formation near zero degrees obtained using Eq. (5): the target is CO₂ and the positron incident energy is 27 eV. Mean (long dash); ± 3 standard deviations from the mean (short dash).

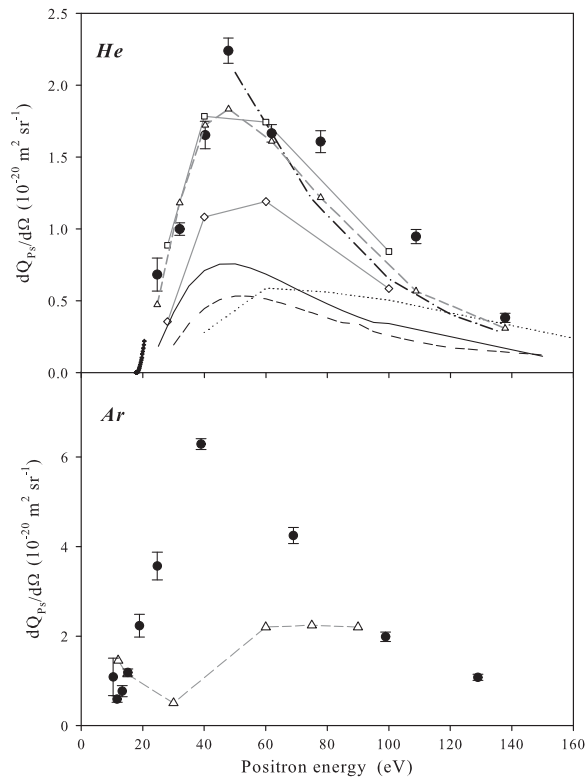

FIG. 3. The experimental absolute differential Ps($n=1$) formation cross section for positron scattering from atoms compared with theoretical results: (bullet) this work. He: (diamond) FBA [16]; (square) DWA [16]; (dotted line) close-coupling [19]; (dash dot) eikonal approximation [21]; (double dash) DWA [25]; (solid line) second order DWA [26]; (triangle) 27-state coupled-pseudostate approach [29,58]; (thick line near the threshold), Kohn variational method [59]. Ar: (triangle) truncated coupled static [24].

In Fig. 3, absolute differential Ps formation cross sections in positron collisions with He and Ar are presented and compared with available theories at zero degrees. For both targets, the experimental data increase with increasing energy to form distinct peaks centered around 50 and 40 eV, respectively. Included for He are the results of calculations performed within various approximations. Of these, the first order Born approximation (FBA) and distorted-wave approach (DWA) of Mandal *et al.* [16] both predict a shape similar to experiment; the DWA also agrees in magnitude. However other DWA results [25,26], although also similar in shape, are considerably lower especially in the peak region. The main differences between the various DWA calculations is in the form of the target wave function used and the fact that exchange was not included explicitly in the work of Mandal *et al.* [16] who multiplied both the differential and integrated cross sections obtained by a factor of 2. The results of an eikonal approximation [21] have a magnitude close to experiment at the lowest energy considered but which decreases at a somewhat faster rate. The close-coupling calculations for positron-helium

scattering are expected to give more accurate results than the methods discussed above as they include a better representation of the target and Ps distortions. The calculations of Chaudhuri and Adhikari [19] which include 5 states of He and 3 of Ps reveal a much broader maximum than seen experimentally and its magnitude is approximately a factor of 4 lower around the peak. A good agreement is found with the more elaborate 27-state coupled-pseudostate approximation of Walters and co-workers [29,58] which include 3 Ps eigenstates, 6 He eigenstates, and 18 He pseudostates. At low energies, the theoretical results display the same rapid rise as experiment and, although they are lower in magnitude at the peak itself, they agree with its the position. In the intermediate region, this theory is approximately (20–30)% below experiment, merging with it at the highest energy considered. The variational results in the Ore gap [59] display a very rapid rise from threshold. The calculations are based on the Kohn variational method for partial waves $l = 0$ to 4 and the Born approximation for $5 \leq l \leq 10$; the uncertainty due to the use of the Born approximation is estimated to be at most (5–10)% [59]. It is worth noting that, over the energy range considered, the differential cross sections predicted by Refs. [29,59] have been found to change by less than 2% over the angular acceptance of the experiment, supporting the assumption made in Eq. (3).

In the case of Ar, the experimental results are compared with the only available theory, a truncated static-coupled approximation [24]. This shows an initial decrease from 10 eV to 30 eV, increasing again at 60 eV, being close to experimental values at 10 and 90 eV.

Differential cross sections for Ps formation from H₂ and CO₂ are shown in Fig. 4. In the case of H₂, the experimental data indicate a peak around 30 eV and are broadly

FIG. 4. Experimental absolute differential cross sections for Ps formation from H₂ and CO₂ (bullet). Two theories are also shown for H₂: (hollow circle) FBA [18]; (square) second-order Born approximation [17].

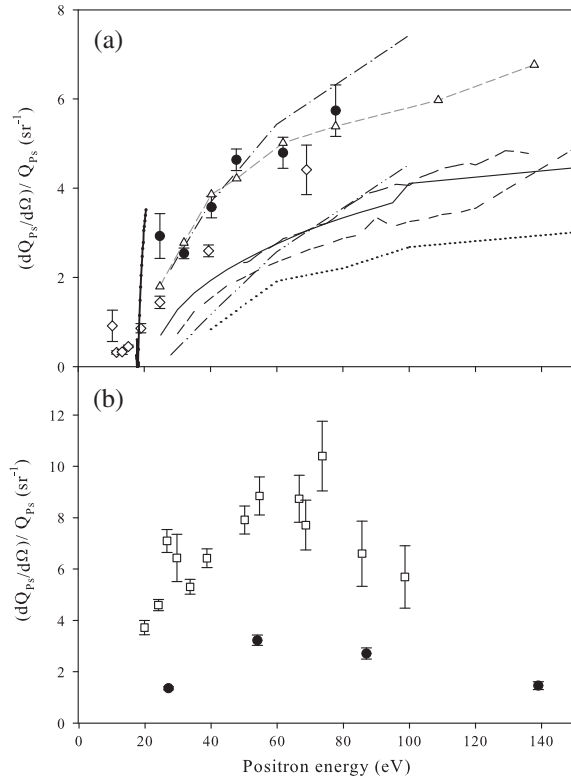

FIG. 5. A comparison of the ratio $(dQ_{Ps}/d\Omega)/Q_{Ps}$ for the atoms and molecules investigated in this work. (a): (bullet) He; (diamond) Ar. Also shown in (a) are $(dQ_{Ps}/d\Omega)/Q_{Ps}$ for the He theories shown in Fig. 3: (dash double dot) FBA [16]; (dash dot) DWA [16]; (dotted line) close-coupling [19,65]; (double dash) DWA [25]; (solid line) second order DWA [26]; (dash) eikonal approximation [21]; (triangle) 27-state coupled pseudostate [29,58]; (thick line near the threshold), Kohn variational method [59]. (b): (square) H₂; (bullet) CO₂.

consistent with the predictions of both first- and second-order Born determinations [17,18]. In the case of CO₂, the differential cross section displays a broad peak between 30 and 90 eV before decreasing at 140 eV.

In order to discern the degree of forward collimation of the Ps formed from each target, the energy dependence of the ratio $(dQ_{Ps}/d\Omega)/Q_{Ps}$ for He and Ar, and H₂ and CO₂ is plotted in Figs. 5(a) and 5(b), respectively. Experimental values have been calculated using the present measurements for $dQ_{Ps}/d\Omega$ and Q_{Ps} (all n) from various experiments [57,60–62]. For He and Ar, this ratio is found to increase with energy, that for He being higher than for Ar. The ratio for H₂ is roughly twice as high as for CO₂. The greater yield of forward collimation for the low- Z targets (He and H₂) may be due to a comparatively weaker (repulsive) static interaction (e.g., Ref. [63]) and/or the influence of the angular momenta of the captured electrons (e.g., Ref. [64]).

Also shown in Fig. 5 are theoretical values for He. Where possible, Q_{Ps} have been sourced from the same papers as the $dQ_{Ps}/d\Omega$ shown in Fig. 3, or from other work which

relies on the same approach (as in the case for the close-coupling approximation [19,65]). However, in all cases except for the results of Refs. [59] and [29], the theoretical ratios should be considered overestimates (by around 20% or so) since their Q_{Ps} refer to $n = 1$ or $n = 1, 2$ only. Even so, bar for those of Mandal *et al.* [16], these ratios are lower than experiment. Once again, a good agreement is found between experiment and the coupled-pseudostate calculation of Ref. [29] for $(dQ_{Ps}/d\Omega)(n = 1)/Q_{Ps}$ (all n) who allowed for $n = 1, 2$ formation explicitly and $n > 2$ through the $1/n^3$ scaling [58]. The Kohn variational theory of Ref. [59], which is limited to energies below the Ps($n = 2$) threshold, indicates a very sharp rise up to a value of ~ 3.5 at 2.6 eV above it; that for the coupled-pseudostate results of [29] appears much more gradual.

In conclusion, the first measurements of the absolute differential Ps formation cross sections have been presented for He, Ar, H₂, and CO₂. This work provides the only experimental test of a considerable body of theoretical work developed on the subject over the past 40 years [8,9,9–16,16–29,29–34,58,59]. In the case of He, the present measurements are in good agreement with the close-coupling results of Refs. [29,58] and are not inconsistent with the near-threshold Kohn variational theory of Ref. [59]. Future lower energy measurements should enable a more stringent discrimination between the two theoretical descriptions. The results for H₂ are broadly consistent with the predictions of both the first- and second-order Born approximations in Refs. [17,18]. We have found that the general shape of the cross sections is similar for all four targets. It is expected that the great sensitivity of theoretical angular-resolved cross sections to the details of the various approximations (as illustrated in Figs. 3 and 5) will also significantly impact on the resolution of the persistent discrepancies for the *integral* Ps formation cross section (e.g., [3]).

The Engineering and Physical Sciences Research Council is gratefully acknowledged for supporting this work under Grant No. EP/J003980/1 and for providing M. S. and S.E.F. with research studentships. The authors would like to thank James Walters and John Humberston for invaluable discussions and, together with Chandana Sinha, for making available tabulated data prior to publication.
