(Received 11 September 2019; revised manuscript received 9 November 2019; published 14 January 2020)

The transition between isotope-mixing and nonmixing states in hydrogen-deuterium mixture plasmas is observed in the isotope (hydrogen and deuterium) mixture plasma in the Large Helical Device. In the nonmixing state, the isotope density ratio profile is nonuniform when the beam fueling isotope species differs from the recycling isotope species and the profile varies significantly depending on the ratio of the recycling isotope species, although the electron density profile shape is unchanged. The fast transition from nonmixing state to isotope-mixing state (nearly uniform profile of isotope ion density ratio) is observed associated with the change of electron density profile from peaked to hollow profile by the pellet injection near the plasma periphery. The transition from nonmixing to isotope-mixing state strongly correlates with the increase of turbulence measurements and the transition of turbulence state from TEM to ion temperature gradient is predicted by gyrokinetic simulation.

DOI: [10.1103/PhysRevLett.124.025002](https://doi.org/10.1103/PhysRevLett.124.025002)

Control of the isotope ratio in the plasma core is one of the crucial issues regarding fusion plasma because the fusion power decreases as the deuterium-tritium (D-T) ratio in the core region deviates from 1∶1. Although the isotope ratio of influx can be easily monitored by  $D_{\alpha}$  and  $T_{\alpha}$  lines, the individual isotope density has not been clarified whether the tritium density profiles are identical to the deuterium density profile. Although the isotope mixture plasma is necessary for this study, there are only a few experiments using the isotope mixture plasma [\[1,2\]](#page-4-0). The hydrogen-deuterium (H-D) mixture plasma experiment in JET demonstrates that the H-D ratio profiles are insensitive to the isotope species of the recycling from the wall in the ion temperature gradient (ITG) dominant regime, where nearly uniform profile of the H-D ratio can be expressed as an isotope-mixing state. Knowledge of the isotope state is limited due to a lack of precise measurements of isotope profiles. In many cases, the ion density profile shape, including the isotope-mixing state, is assumed to be identical to the electron density profile due to the quasineutrality. However, in the isotope mixture plasmas, the individually different isotope ion profiles are possible as long as the ambipolar condition is maintained, but the nonmixing state has never been observed experimentally so far. In recent work with gyrokinetic simulations, the nonmixing state is predicted in the TEM regime, while the isotope-mixing state is predicted in the ITG regime [\[2\]](#page-4-1). There are also earlier works on the gyrokinetic simulations for the turbulent transport of the multiple isotope ions [\[3](#page-4-2)–5].

In this Letter, we show a novel observation of evidence of the formation the nonmixing profile and its transition to the isotope-mixing state in the plasma associated with the increase of turbulence level propagating in the ion diamagnetic direction. These results demonstrate that either of two isotope states (nonmixing or isotope mixing) can exist in the H-D mixture plasma depending on the turbulence state as predicted by the gyrokinetic simulations. A bulk charge exchange spectroscopy system [\[6](#page-4-3)–9] has been applied to measure the radial profiles of  $n_H/(n_H+n_D)$ and  $n_D/(n_H + n_D)$  in the plasma from  $H_\alpha$  and  $D_\alpha$  lines emitted by the charge exchange reaction between the bulk ions and the neutral beam injected in the Large Helical Device (LHD) [\[10](#page-4-4)–12]. In order to study whether the ion particle transport is in the nonmixing state or the isotopemixing state, the hydrogen and deuterium density profiles are measured in the plasmas with core hydrogen fueling by the H beam and edge deuterium fueling by recycling  $(\Gamma_D > \Gamma_H)$ , where  $\Gamma_D$  and  $\Gamma_H$  are the influx of deuterium and hydrogen evaluated with passive spectroscopy.

Figure [1](#page-1-0) shows radial profiles of electron density normalized by the line-averaged electron density. The line-averaged electron density increases from 2 to  $4 \times 10^{19}$  m<sup>-3</sup> shot by shot due to increasing the hydrogen recycling,  $\Gamma_H/\Gamma_D$ , from 0.3 to 0.8. The electron density profile shapes are almost identical for these three discharges with different line-averaged density and different wall recycling isotope ratio. However, radial profile shapes of hydrogen and deuterium density are quite different depending on the ratio of hydrogen recycling. The amount of hydrogen density increases as the hydrogen recycling is increased, although the amount of deuterium density is similar for these three discharges. The increase of density is mainly due to the increase of hydrogen recycling from the wall. When the isotope recycling ratio is close to unity, there is almost no difference in profiles between hydrogen and deuterium as seen in Fig. [1\(b\).](#page-1-0) In contrast, a significant difference in the profile shape (peaked or hollow) between hydrogen density and deuterium density is observed in the lower density plasma where the hydrogen recycling is low enough ( $\Gamma_H/\Gamma_D = 0.3$ ), as seen in Fig. [1\(d\)](#page-1-0). These results clearly show the nonmixing state where the isotope density profiles strongly depend on the location of the isotope source.

As seen in Fig. [2](#page-1-1), the isotope fraction of the bulk species,  $n_{\rm H}/(n_{\rm H}+n_{\rm D})$  for the H beam and  $n_{\rm D}/(n_{\rm H}+n_{\rm D})$  for the D beam, shows a clear peaked profile when the isotope fraction of influx by wall recycling (indicated by arrows) is low. The isotope fraction at the last closed flux surface

<span id="page-1-0"></span>

FIG. 1. (a) Radial profiles of electron density and (b),(c),(d) radial profiles of H and D density in the plasma with H-beam fueling for the different line-averaged density and wall recycling isotope ratio of (b)  $3.8 \times 10^{19}$  (Γ<sub>H</sub>/Γ<sub>D</sub> = 0.8), (c)  $3.1 \times 10^{19}$  $(\Gamma_H/\Gamma_D = 0.5)$ , and (d)  $1.9 \times 10^{19}$  m<sup>-3</sup> ( $\Gamma_H/\Gamma_D = 0.3$ ).

 $(r_{\text{eff}}/a_{99} = 1)$  decreases as the isotope fraction of influx is decreased. The hydrogen density is peaked in the plasma with hydrogen beam fueling and deuterium density is peaked in the plasma with deuterium beam fueling when the recycling of the beam species is low enough. In contrast, when the isotope fraction of beam species is close to 0.5 (the hydrogen influx is identical to the deuterium influx) the isotope fraction profiles become flat. These results show clearly that the peaking of the isotope density is due to the fueling location rather than the transport difference between deuterium and hydrogen. The nonmixing state can be observed more clearly when the recycling of the beam fueling species is low enough  $( $0.3$ ).$ 

The transition from nonmixing state to isotope-mixing state is observed after H and D pellet injections. The peak of the pellet deposition is  $r_{\text{eff}}/a_{99} \sim 0.9$  in these plasma conditions, which are evaluated experimentally from the increment of the electron density [\[13\]](#page-4-5). Because of the relatively shallow pellet deposition, pellet injections make the electron density profile more hollow. Figure [3](#page-2-0) shows the change of radial profiles of H and D density by H-pellet and D-pellet injection in the target plasma with H-beam fueling and with low hydrogen recycling influx. After the H-pellet injection, the H density shows the significant increase, while the profile of D density is almost unchanged except for near the plasma periphery of  $r_{\text{eff}}/a_{99} > 0.85$ . In contrast, the significant increase of H density as well as of D density is observed in the case of D-pellet injection. This result indicates the fast redistribution of the H-density profile due to the additional fast transport process after the

<span id="page-1-1"></span>

FIG. 2. Radial profiles of (a) the hydrogen isotope fraction,  $n_{\rm H}/(n_{\rm H}+n_{\rm D})$  with H-beam fueling and (b) the deuterium isotope fraction,  $n_D/(n_H + n_D)$  with D-beam fueling. The isotope fractions of recycling are indicated with arrows at the right y axis.

<span id="page-2-0"></span>

FIG. 3. Radial profiles of hydrogen (H) and deuterium (D) density in the plasma with H-beam fueling before ( $\Delta t < 0$ ) and after  $(\Delta t > 0)$  (a) hydrogen pellet (No. 142315) and (b) deuterium pellet (No. 142314). The peak of deposition of pellets is located at  $r_{\text{eff}}/a_{99} \sim 0.9.$ 

D-pellet injection. Before the pellet injection the hydrogen density profile is much more peaked than the deuterium density profile due to the hydrogen beam fueling and deuterium dominant recycling. After the pellet injection the hydrogen density profile becomes similar in shape to the deuterium density profile regardless of the species of pellet.

This change in the hydrogen and deuterium density profile by the pellet injection demonstrates the change of states from nonmixing to isotope mixing as clearly shown in the radial profile of the isotope fraction in Fig. [4.](#page-2-1) Before the pellet injection, the hydrogen fraction profile is significantly peaked and the hydrogen fraction profile becomes flat after the hydrogen pellet near the plasma periphery. The flattening of the hydrogen fraction profile is also observed in the deuterium pellet, although the peaking of the hydrogen fraction profile is expected by the deposition of the deuterium pellet. Therefore, the flattening of the hydrogen fraction profile both for the hydrogen and the deuterium pellet is clear evidence for isotope mixing. If the plasma is a nonmixing state, the hydrogen fraction profile should be more peaked after the deuterium pellet injection because of the edge-pellet deposition. The transition from nonmixing state to isotope-mixing state occurs in a shorter time (less than ∼15 ms), which implies the large ion diffusion coefficient in the isotope-mixing state.

Figure [5](#page-2-2) shows how the turbulence changes before  $(t = 3.73)$  and after  $(t = 3.77 \text{ sec})$  pellet injection, which corresponds to the nonmixing and isotope-mixing states, respectively. Figure [5\(a\)](#page-2-2) shows the density fluctuation spectrum integrated from edge to core along the laser

<span id="page-2-1"></span>

FIG. 4. Radial profiles of the hydrogen isotope fraction,  $n_{\rm H}/(n_{\rm H}+n_{\rm D})$  before and after the (a) H pellet (No. 142315) and (b) D pellet (No. 142314).

<span id="page-2-2"></span>

FIG. 5. (a) Density fluctuation spectrum in the nonmixing and isotope-mixing states in Fig. [4\(a\)](#page-2-1) and contour of density fluctuation in the space of the normalized minor radius and phase velocity for (b) the nonmixing state and (c) isotope-mixing state (No. 142315). Radial profiles of the projection of  $V_{E\times B}$  to the PCI observation plane are also plotted.

beam line of the central chord of phase contrast imaging (PCI) [14–[16\].](#page-4-6) The wave number of the turbulence measured in this plasma is  $0.2-0.4$  mm<sup>-1</sup>. Both turbulence modes at high frequency (high phase velocity) and low frequency (low phase velocity) increase by an order of magnitude in the isotope-mixing state. The radial profiles of poloidal rotation velocity measured with charge exchange spectroscopy are also overplotted in Figs. [5\(b\)](#page-2-2), [5\(c\).](#page-2-2) Turbulence measured with PCI has  $E \times B$  drift, the propagation direction with respect to the  $E \times B$  drift is important to determine the type of the turbulence. The contour of density fluctuation in the space of normalized minor radius and phase velocity shows that there are two turbulence modes in the isotope-mixing state after the pellet injection. One is the turbulence propagating with  $E \times B$ drift and the other is near edge turbulence propagating in the ion diamagnetic direction. The increase of turbulence and the appearance of ion diamagnetic propagating turbulence is clearly observed associated with the transition from nonmixing and isotope-mixing states.

Figures [6\(a\)](#page-3-0), [6\(b\)](#page-3-0) show the electron density, electron temperature, and ion temperature profiles for nonmixing and isotope-mixing states. Figure [6\(c\)](#page-3-0) shows the linear growth rates calculated with gyrokinetic simulation code GKV [\[17\]](#page-4-7) for TEM and ITG turbulence, based on the radial

<span id="page-3-0"></span>

FIG. 6. Radial profile of (a) the electron density and (b) the electron and ion temperature before pellet injection (nonmixing state) and after pellet injection (isotope mixing state), and (c) the linear growth rate at  $r_{\text{eff}}/a_{99} = 0.8$  for the nonmixing and isotope-mixing states calculated with GKV.

profile of the density and the temperature measured. The nonmixing state is observed in the low-density plasmas  $(n_e \sim 1.5 \times 10^{19} \text{ m}^{-3})$  with electron cyclotron heating (ECH) and neutral beam injection (NBI), where the beam fueling isotope species differ from the isotope species due to recycling. The power of ECH is 2 and the power of NBI is 4.2 MW. The  $n_{\rm H}/(n_{\rm H}+n_{\rm D})$  density profile is peaked for H beam fueling and D recycling wall conditions. After the pellet injection, the isotope-mixing state is observed in higher density plasmas ( $n_e \sim 2.5 \times 10^{19}$  m<sup>-3</sup>). As seen in Fig. [6\(b\),](#page-3-0) electron temperature and its normalized gradient  $(R_{ax}/L_T)$  decreases significantly but ion temperature decreases slightly. The ratio of electron temperature to ion temperature ( $T_e/T_i$  ratio) also decreases. Here,  $R_{ax}$  is a major radius of magnetic axis and  $L_{T_e}$  and  $L_{T_i}$  are the inverse of logarithmic gradients,  $(\partial \ln T_e/\partial r)^{-1}$  and  $(\partial \ln T_i/\partial r)^{-1}$ , respectively. The  $T_e/T_i$  ratio and the normalized  $T_e$  gradient  $(R_{ax}/L_{T_e})$  at  $r_{\text{eff}}/a_{99} = 0.8$ decreases from 1.73 to 1.30 and from 19.3 to 11.6, respectively, while the normalized  $T_i$  gradient  $(R_{ax}/L_{T_i})$ increases slightly from 11.1 to 13.8. The impact of the collisionality in isotope plasmas and the sign of the density gradient on TEM and ITG mode is studied in LHD using gyrokinetic simulation [\[18](#page-4-8)–20]. When the sign of density gradient changes from negative  $[\partial n_e/\partial r(0.8) < 0$ : peaked] to positive  $[\partial n_e/\partial r(0.8) > 0$ : hollow], the growth rates of both TEM and ITG decrease. The gyrokinetic simulation predicts that TEM propagating in the electron diamagnetic direction is unstable for the nonmixing state. However, the TEM is stabilized and ITG mode propagating in the iondiamagnetic direction becomes unstable for the isotopemixing state. The mode transition from TEM to ITG mode is due to the decrease of the  $T_e/T_i$  ratio, increase of collisionality ( $n_e$  rise and  $T_e$  drop), and sign flip of the electron density gradient from negative (peaked profile) to positive (hollow profile).

Effective diffusion coefficient of particle transport,  $D_s = -\Gamma_s^{(GK)}/(\partial n_s/\partial r)$ , for ion (s = i) and for electron  $(s = e)$  are evaluated from the quasilinear approximation in the gyrokinetic calculations. The ratio of ion diffusion to electron diffusion coefficient  $D_i/D_e$  is 0.4 for the case of the TEM dominant state before the pellet injection, while  $D_i/D_e$ is 2.5 for the case of the ITG-dominant state after the pellet injection. When the electron particle diffusion is dominant  $D_e > D_i$ , the radial profile of each isotope species can differ depending on the source location of each species (nonmixing state). In contrast, when the ion particle diffusion is dominant  $D_i > D_e$ , the radial profile of each isotope species becomes identical due to the large diffusion (isotope-mixing state). The electron and ion diffusion coefficient evaluated from the quasilinear gyrokinetic calculations well reproduces the qualitative tendency of the nonmixing and isotopemixing states observed in the experiment. Although nonlinear gyrokinetic simulation for multiple ion species in

LHD plasmas is numerically challenging, the systematic investigations of correlations among the turbulent particle transport levels, its direction, and the driving microinstabilities are useful for more quantitative comparisons with the above experimental results. Also, the gyrokinetic simulations for the transient phase, which will remain as future works, can clarify the threshold between the isotope-mixing and the nonmixing states. The nonlinear turbulence simulations, which are important for making quantitative comparisons, will be addressed in the future.

In conclusion, both the nonmixing and the isotopemixing states are observed in the hydrogen-deuterium mixture plasma in the LHD. The nonmixing state is observed in the slightly peaked density plasma with low recycling beam fueled plasma and the isotope fraction profiles depend on the location of the isotope source (core beam fueling or edge influx due to recycling). The isotopemixing state is observed in the hollow density plasma after the pellet injection and the isotope fraction profile becomes flat regardless of the location of the isotope source. This paper reports important findings on the nonmixing state between the hydrogen and deuterium ions in the H-D mixture plasma. This finding implies that the nonmixing state between deuterium and tritium ions could be also achieved in the D-T mixture plasma in JET and ITER depending on the turbulence state and gives insight for controlling the isotope ratio profile in future fusion devices.

The authors wish to thank the LHD experiment group for the excellent support of this work. K. I. acknowledges Dr. M. Yoshida (National Institutes for Quantum and Radiological Science and Technology; QST) for providing us with two spectrometers for the bulk charge exchange spectroscopy.
