(Received 15 May 2020; revised 8 January 2021; accepted 22 January 2021; published 12 March 2021)

A direct measurement of the decay width of the excited  $0^+_1$  state of <sup>6</sup>Li using the relative self-absorption technique is reported. Our value of  $\Gamma_{\gamma,0_1^+\to 1_1^+} = 8.17(14)_{\text{stat}}(11)_{\text{syst.}}$  eV provides sufficiently low experimental uncertainties to test modern theories of nuclear forces. The corresponding transition rate is compared to the results of ab initio calculations based on chiral effective field theory that take into account contributions to the magnetic dipole operator beyond leading order. This enables a precision test of the impact of two-body currents that enter at next-to-leading order.

DOI: [10.1103/PhysRevLett.126.102501](https://doi.org/10.1103/PhysRevLett.126.102501)

Nuclear structure physics has entered an era of precision studies, both in experiment and theory. For light nuclei, ab initio theory based on interactions from chiral effective field theory [\[1\]](#page-4-2) is reaching an accuracy at which corrections to electromagnetic (EM) operators that emerge naturally in the chiral expansion become relevant. A recent review [\[2\]](#page-4-3) indicates that precision measurements of EM transition rates with uncertainties of a few percent or better are required to explore and validate the effects of these subleading corrections. For few-nucleon systems, direct measurements of strong transition rates with such precision are often challenging experimentally owing to the very short lifetimes involved.

The present study is focused on the nucleus <sup>6</sup>Li in its excited  $0^{+}_{1}$  state at  $E_{0^{+}_{1}} = 3562.88(10)$  keV [\[3\]](#page-4-4), which constitutes the lightest nonstrange hadronic system [\[4\]](#page-4-5) with a dominant internal EM decay branch to its  $1^+_1$  ground state. The potentially competing parity-forbidden decay via  $\alpha$ emission has not been observed, and it is at least ten million times weaker than the  $\gamma$  decay [\[5\].](#page-4-6) Because of its occurrence as stable matter (compared to the lighter hypernuclei [\[6\]](#page-4-7)) and the low nucleon number of <sup>6</sup>Li, the decay of its  $0^+_1$ state is the EM transition of the simplest hadronic system, which is simultaneously accessible by precision studies in theory and experiment. It is, therefore, ideally suited for testing our understanding of nuclear forces and EM currents in a many-nucleon system. Moreover, this is the EM-analog transition to the <sup>6</sup>He beta decay, whose rate was recently measured with high precision [\[7\],](#page-4-8) so that this  $A = 6$  system in future offers a comprehensive test of electroweak interactions in light nuclei.

On the theory side, significant progress has been made in chiral effective field theory ( $\chi$ EFT) [\[1,8\]](#page-4-2) and in the *ab initio* solution of the quantum many-body problem for light nuclei [\[9,10\].](#page-4-9) Recently, the focus has been on the consistent inclusion of electroweak transition operators [\[2\],](#page-4-3) with a focus on the impact of two-body currents (2BC). For EM transitions in light nuclei, calculations with traditional 2BC and potentials were performed in Ref. [\[11\],](#page-5-0) while calculations with 2BC from  $\chi$ EFT used in conjunction with wave functions derived from traditional potentials were performed in Ref. [\[12\]](#page-5-1), reaching a precision at the few-percent level. In Ref. [\[13\]](#page-5-2), this transition and the magnetic moment of the ground state of <sup>6</sup>Li were calculated with interactions from  $\chi$ EFT without 2BC. Similarly, these observables have been studied in Refs. [\[14](#page-5-3)–16]. In this Letter, we will present the first calculations obtained with 2BC and consistent

<span id="page-1-0"></span>

FIG. 1. (a)–(c) Previous measurements of the B(M1;  $1^+_1 \rightarrow 0^+_1$ ) strength for <sup>6</sup>Li with the methods of relative NRF [\[19,20\]](#page-5-6) (a), SAbs [\[20](#page-5-7)-25] (b), and  $(e, e')$  [26-[30\]](#page-5-8) (c). For each experimental method, the data are sorted by the time of publication, with the most recent data point on the right. A label next to the data points indicates the year of publication and the last name of the first author. Low-q data of the most precise  $(e, e')$  result by Bergstrom *et al.* [\[30\]](#page-5-11) and a possible quartic polynomial extrapolation (see also the Supplemental Material [\[31\]\)](#page-5-13) of  $B(M1, q)$  to the photon point  $(q_0)$  are shown as an uncertainty band in (d). The present result, which can be interpreted as a measurement at  $q_0$ , is given in panel (e). Panel (f) shows the result of four theoretical calculations from the present work (see also Fig. [3\)](#page-4-10) with estimated uncertainties of the many-body method. They employed different Hamiltonians that are indicated by different colors and the labels below the data points and include the leading two-body currents.

interactions derived from  $\chi$ EFT. In the case of weak  $\beta$ decays, this has been shown to lead to a systematic improvement between experiment and theory [\[17\]](#page-5-4).

From the experimental side, the determination of the isovector magnetic dipole transition strength  $B(M1; 0^+_{1,T=1} \rightarrow 1^+_{1,T=0}) \propto E_\gamma^{-3} \Gamma_{\gamma,0^+_{1}\rightarrow 1^+_{1}}$  between the first excited  $0^+_1$  state of <sup>6</sup>Li with a total isospin quantum number of  $T = 1$  and the  $T = 0$  ground state, which is proportional to the product of the level width for  $\gamma$  decay  $\Gamma_{\gamma,0_1^+ \to 1_1^+}$  and a γ-ray energy  $(E<sub>y</sub>)$  dependent factor, has been the subject of considerable effort in the past. The extremely short half-life of the excited state of about 80 attoseconds  $(10^{-18}$  s) [\[3\]](#page-4-4) makes a direct measurement of its decay rate impossible [\[18\]](#page-5-5). Panels (a)–(c) of Fig. [1](#page-1-0) show the history of published values for this quantity as compiled in the Evaluated Nuclear Structure Data Files (ENSDF) [\[3\]](#page-4-4). These values have been obtained using three different techniques: nuclear resonance fluorescence (NRF) relative to another transition (relative NRF) [\[19,20\]](#page-5-6), self-absorption (SAbs) [\[20](#page-5-7)–25], and inelastic electron scattering  $(e, e')$  [\[26](#page-5-8)–30]. In the ENSDF, a weighted average value of  $B(M1)_{\text{ENSDF}} =$ 15.65(32)  $\mu_N^2$  [from  $\Gamma_{\gamma,0_1^+ \to 1_1^+} = 8.19(17)$  eV [\[3,32\]](#page-4-4) ], is derived from a selection of three of the most recent publications in Ref. [\[33\].](#page-5-9) The selection excludes earlier measurements with obvious systematic deviations [for comparison: a weighted average of all measurements yields a value of  $B(M1) = 14.53^{+0.20}_{-0.30} \mu_N^2$ . Regardless of the averaging procedure, the final result is strongly dominated by two  $(e, e')$  results of Eigenbrod [\[29\]](#page-5-10) and, in particular, of Bergstrom *et al.* [\[30\],](#page-5-11) that claim the highest precision. In such an  $(e, e')$  experiment, the  $B(M1)$  value is obtained in a model-dependent way from the measured form factor  $|F(q)|^2$ , where q denotes the momentum transfer. Both works employed the plane-wave Born approximation to obtain the q-dependent  $B(M1, q)$  from  $|F(q)|^2$  [\[34\]](#page-5-12), which is equal to the  $B(M1)$  strength in the limit of the minimum necessary momentum transfer  $q_0 = E_{0_1^+}/\hbar c \approx 0.018$  fm, the so-called "photon point." Panel (d) of Fig. [1](#page-1-0) shows  $B(M1, q)$  values obtained from the form factor of Bergstrom *et al.* [\[30\]](#page-5-11), along with an uncertainty band from one possible extrapolation in our attempt to reproduce their results [\[31\]](#page-5-13). Similar to Refs. [\[29\]](#page-5-10) and [\[30\]](#page-5-11), the present extrapolations employed fits of low- $q$  expansions of the model-independent energy dependence of the form factor with different cutoffs to varying subsets of the low- $q$  data. In order to match the width of the uncertainty band to the data point of Bergstrom et al., the selection of fits had to be limited to a reduced chi-square  $\chi^2_{\nu}$  on the order of 0.1. It was found that the width of this band can easily be extended by increasing the cutoff or relaxing the restriction on  $\chi^2_{\nu}$ . The obvious presence of systematic uncertainty in the literature data precludes a comparison to state-of-the art theoretical results [\[2,12\]](#page-4-3) and calls for a precision measurement directly at the photon point to avoid the extrapolation uncertainty.

<span id="page-1-1"></span>We have, therefore, performed an experiment to measure  $\Gamma_{\gamma,0_1^+\rightarrow 1_1^+}$  with the newly developed NRF-based relative SAbs method [\[35,36\].](#page-5-14) Compared to the traditional SAbs technique [\[37\]](#page-5-15) used in several previous experiments [\[20](#page-5-7)–25], it uses a normalization target (no) in combination with the scattering target of interest (sc) to separate resonant and nonresonant processes (a detailed derivation of this equation can be found in the Supplemental Material [\[31\]\)](#page-5-13):

$$
R_{\rm exp} = 1 - \left\langle \frac{N_{\rm no}^{\rm nrf}}{N_{\rm no}^{\rm abs}} \right\rangle \frac{N_{\rm sc}^{\rm abs}}{N_{\rm sc}^{\rm nrf}} = R(\Gamma_{\gamma,0_1^+ \to 1_1^+}, T_{\rm eff}). \tag{1}
$$

In Eq. [\(1\)](#page-1-1),  $N_{\rm x}^{\rm mf}$  denotes the number of observed NRF events from a  $\gamma$ -ray line from material x. The number of events is reduced to  $N_{\rm x}^{\rm abs}$  in a second measurement by the introduction of an absorber target, which consists of the same material as the scatterer of interest, into the incident continuous-energy photon beam. The reduction of the count rate of the NRF line of interest is due to nonresonant scattering as well as the SAbs induced by the absorber. Both contributions can be separated in a model-independent way by using the reduction of the count rate in the NRF lines of the normalization target [factor  $\langle N_{\text{no}}^{\text{nrf}}/N_{\text{no}}^{\text{abs}} \rangle$  in Eq. [\(1\)\]](#page-1-1), which is due to nonresonant effects, only. In the absence of other decay branches,  $R_{exp}$  is directly related to  $\Gamma_{\gamma,0_1^+\rightarrow 1_1^+}$  [\[37,69\]](#page-5-15) [see Eq. [\(1\)](#page-1-1)] once the thermal motion of the nuclei of interest is taken into account. It can be treated in terms of an effective temperature  $T_{\text{eff}}$  [\[37,38,69\]](#page-5-15) that includes corrections due to condensed-matter effects in the target material (see below).

The experiment was performed at the Darmstadt High-Intensity Photon Setup [\[39\],](#page-5-16) with continuous-energy photon beams generated by bremsstrahlung processes of a 7.1(2) MeV electron beam of the Superconducting Darmstadt Linear Accelerator [\[40,70\]](#page-5-17) on a copper radiator. A scattering target composed of 5.033(5) g [particle areal density  $d_{\text{sc},\text{Li}} = 0.02773(6) \text{ b}^{-1}$ , using a target diameter of 20.00(5) mm] of lithium carbonate  $(Li_2CO_3)$  enriched to  $95.00(1)$ % in <sup>6</sup>Li, sandwiched between pure boron normalization targets of 2.118(5) g and 2.119(5) g with a 99.52(1)%  $11B$  enrichment, was measured for about 122 h. A second measurement, 186 h, was carried out with a 9.938(5) g  $[d_{\text{abs}}] = 0.05469(10)$  b<sup>-1</sup>] absorber of the same  $Li_2CO_3$  material. Scattered  $\gamma$  rays from the target were detected by three high-purity germanium detectors at polar angles of 90° (twice) and 130° with respect to the beam axis. To avoid direct scattering of  $\gamma$  rays from the absorber target into the detectors, the target was mounted at the entrance of the 1 m-long collimation system of the Darmstadt High-Intensity Photon Setup, which acts as a passive shielding. The direct scattering into the detectors was found to be negligible by an additional 8 h measurement with the absorber target only. A potential systematic uncertainty due to small-angle scattering of bremsstrahlung  $\gamma$  rays inside the collimator, which would then induce excess NRF reactions in the scatterer, was found to be on the order of 0.33% by GEANT4 [41–[43\]](#page-5-18) simulations (i.e., in the anticipated order of magnitude of the uncertainty of  $R$ ) and taken into account by replacing  $\langle N_{\text{no}}^{\text{nf}}/N_{\text{no}}^{\text{abs}} \rangle$  with  $1.0033 \times \langle N_{\text{no}}^{\text{nrf}}/N_{\text{no}}^{\text{abs}} \rangle$  in Eq. [\(1\)](#page-1-1). The summed spectra of all three detectors from the measurements with and without absorber are provided in Fig. [2.](#page-2-0) Using the known internal γ-ray transitions of <sup>11</sup>B at 2125, 4445, and 5020 keV [\[44\]](#page-5-19),

<span id="page-2-0"></span>

FIG. 2. Summed spectra of the three detectors from the measurement with (gold) and without (black) the <sup>6</sup>Li absorber. For better visibility, the spectrum with the absorber was shifted by 100 keV to higher energies. The observed NRF events of three transitions of  $11B$  were used to normalize the spectrum with the absorber, so that the difference in counts for the <sup>6</sup>Li transition is due to SAbs only. On the right-hand side of the transitions of interest, the (absolute) value of the SAbs  $(R_{exp})$  is indicated, which is expected to be zero for  $^{11}B$ .

the measurement with the absorber was normalized to the one without it using the energy-dependent factor  $N_{\text{no}}^{\text{nrf}}/N_{\text{no}}^{\text{abs}}$ <br>in Eq. [\(1\).](#page-1-1) The normalization factor at the three discrete energies of the  $11B$  transitions were interpolated by a GEANT4 simulation of the  $\gamma$ -ray attenuation, which was in turn validated by an off-line measurement with a radioactive <sup>56</sup>Co source. Including the counting statistics and the correction factor for small-angle scattering and propagating uncertainties with a Monte Carlo method [\[45\]](#page-6-0), a value of  $R_{\text{exp}} = 0.5192(20)$  with a relative uncertainty of 0.39% was obtained.

 $Li<sub>2</sub>CO<sub>3</sub>$  was chosen as the target material to reduce systematic uncertainties because pure lithium, used in all previous experiments [19–[30\],](#page-5-6) is highly hygroscopic, which may lead to systematic errors in the determination of the target thickness. The  $T_{\text{eff}}$  value for  $Li_2CO_3$  [see Eq. [\(1\)](#page-1-1)] was determined from state-of-the-art atomic theory. First, the phonon density of states of  $Li<sub>2</sub>CO<sub>3</sub>$  was obtained from density functional theory [\[71,72\].](#page-6-1) Computations of this observable are typically in excellent agreement with experimental data [\[73,74\]](#page-6-2). The density functional theory calculations employed the GPAW [\[75,76\]](#page-6-3) code in a planewave basis. For the exchange-correlation (xc) potential, the local-density approximation (LDA) [\[77\]](#page-6-4) and the generalized-gradient approximation (GGA) [\[78\]](#page-6-5) were tried. These approximations typically slightly underestimate (LDA) and overestimate (GGA) the crystal binding. Both xc potentials reproduced the experimental lattice constants  $a, b, c$ , and  $\gamma$ of  $Li_2CO_3$  [\[79\]](#page-6-6) with deviations at the 0.1% level; this can be viewed as a benchmark test. From the phonon density of states, a value of  $T_{\text{eff}} = 411(11)$  K was obtained by

the procedure described in Ref. [\[38\]](#page-5-20), which represents the average value and spread of the LDA and GGA solutions. Using all the aforementioned input [\[31\]](#page-5-13), our experimental value for the *γ*-decay width is  $\Gamma_{\gamma,0_1^+ \to 1_1^+} =$  $8.17^{+0.14}_{-0.13}$  (stat.) $^{+0.10}_{-0.11}$  (syst.) eV, which corresponds to a strength  $B(M1;0^+ \rightarrow 1^+) = 15.61^{+0.27}_{-0.25}$  (stat.) $^{+0.19}_{-0.21}$  (syst.) $\mu_N^2$ . The 68.3% coverage interval (CI) is divided into statistical (stat.) and systematic (syst.) parts, where the latter accounts for uncertainties in the target dimensions as well as in atomic and condensed-matter contributions. (Since both contributions are uncorrelated and the CIs are almost symmetric, a symmetrized and quadratically summed uncertainty of  $15.61(33) \mu_N^2$  is used in all figures.)

For the ab initio calculations, the importance-truncated no-core shell model (IT-NCSM) [\[80,81\]](#page-6-7) was employed as a state-of-the-art many-body method. Within the IT-NCSM, two-nucleon (NN) and three-nucleon (3N) interactions derived within χEFT were used. Four different Hamiltonians (I–IV) were considered, including (I) the Entem-Machleidt (EM) NN interaction at  $N<sup>3</sup>LO$  [\[82\]](#page-7-0), complemented with a local 3N interaction (cutoff  $\Lambda = 500$  MeV,  $c_D = 0.8$ ) at N<sup>2</sup>LO, which is fitted to reproduce the binding energy as well as the β-decay half-life of <sup>3</sup>H [\[83,84\].](#page-7-1) Furthermore, Hamiltonians (II-IV) use the NN interactions by Entem, Machleidt, and Nosyk (EMN) at N<sup>2</sup>LO, N<sup>3</sup>LO, and N<sup>4</sup>LO with  $\Lambda =$ 500 MeV [\[8\]](#page-4-11), complemented with consistent nonlocal 3N interactions up to  $N^2LO$ ,  $N^3LO$ , and  $N^3LO$ , respectively. The NN interactions were only fitted to NN scattering data and the deuteron binding energy, while the 3N interactions were fitted to reproduce the triton binding energy and to optimize the ground-state energy and radius of <sup>4</sup>He, which led to the values  $c_D = -1$ ,  $c_D = 2$ , and  $c_D = 3$ , for the cases II, III, and IV, respectively. The similarity renormalization group (SRG) was employed at the NN and 3N level with a flow parameter of  $\alpha = 0.08$  fm<sup>4</sup> [\[85,86\]](#page-7-2).

Using an SRG-transformed Hamiltonian requires a consistent SRG transformation of the M1 operator. In previous studies [13–[16\],](#page-5-2) this consistent treatment was neglected. Here SRG corrections of the M1 operator were included at the two-body level. In addition to the SRG correction, the next-to-leading order (NLO) 2BC contributions to the M1 operator were included as well. At NLO, these are commonly expressed as a sum of two contributions: the "intrinsic" term and the "Sachs" term [\[87\]](#page-7-3):

with

$$
\mu_{[12]}^{\text{intrinsic}}(k) = -\frac{i}{2} \nabla_q \times J(q,k) \Big|_{q=0}
$$
  

$$
\mu_{[12]}^{\text{Sachs}}(R,k) = -\frac{i}{2} e(\tau_1 \times \tau_2)_z R \times \nabla_k v(k).
$$

 $\mu_{[12]}^{\text{NLO}}(R,k) = \mu_{[12]}^{\text{intrinsic}}(k) + \mu_{[12]}^{\text{Sachs}}(R,k)$  (2)

<span id="page-3-0"></span>TABLE I. Results of the theoretical calculations for  $B(M1; 0^+_{1,T=1} \rightarrow 1^+_{1,T=0})$  and  $\mu(1^+_{1,T=0})$  of <sup>6</sup>Li. These employed four different Hamiltonians (I–IV), which are introduced in the text. The calculations are sorted by the type of M1 operator, with the same abbreviations as in Fig. [3.](#page-4-10) For comparison, the results of QMC calculations in Refs. [\[11,12\]](#page-5-0) are shown in the second part of the table. The "standard nuclear physics approach" (SNPA) for the operator in Ref. [\[11\]](#page-5-0) was complemented by a  $\chi$ EFT approach in Ref. [\[12\]](#page-5-1), while in both cases phenomenological potentials were used. "LO" refers to one-body currents and "Total" to the inclusion of two-body currents.

Here,  $\tau_i$  are the Pauli matrices, q the momentum transfer of the photon,  $v(\mathbf{k})$  the one-pion exchange potential in momentum representation, and  $\boldsymbol{R}$  the center of mass coordinate of the two nucleons. The Sachs term only depends on the potential between the two nucleons, whereas the translationally invariant intrinsic term is given by the spatial part of the two-body current J. For each interaction, an IT-NCSM calculation was carried out with  $N_{\text{max}}$  from 2 to 12 with harmonic-oscillator frequencies  $\hbar \Omega = 16, 20, 24$  MeV. For the resulting value of the magnetic moment and the transition strength, the central value for the highest  $N_{\text{max}}$  was used as the nominal result, and the neighboring results as an estimate for the many-body uncertainties. The results of the calculations are listed in Table [I](#page-3-0) and displayed in Fig. [3](#page-4-10) [see also panels (e) and (f) of Fig. [1\]](#page-1-0), where they are compared to the new experimental constraint of the present work and the magnetic moment  $\mu(1_{1,T=0}^+) = 0.82205667(26) \mu_N$  [\[3\]](#page-4-4) of the ground state of <sup>6</sup>Li.

Remarkably, the results of the most complete calculations, including contributions from the 2BC to the M1 operator, exhibit an excellent agreement with the new experimental constraints of the present work. This indicates the importance of 2BC for a correct description of the <sup>6</sup>Li nucleus. The residual differences between experiment and

<span id="page-4-10"></span>

FIG. 3. Results for  $B(M1; 0^+_{1,T=1} \to 1^+_{1,T=0})$  and  $\mu(1^+_{1,T=0})$  from theoretical calculations based on Hamiltonians I–IV (see also Table [I](#page-3-0)). As shown in the upper legend, circular markers indicate calculations with the unevolved leading-order (LO) one-body transition operator, triangular markers indicate calculations with the consistently SRG-transformed operator (LO SRG ev.), and quadratic markers indicate the calculations with a consistently SRG-transformed operator including contributions from next-toleading order 2BC (NLO SRG ev.). The labeled arrows illustrate the impact of the two aforementioned improvements. Figure [1](#page-1-0) shows only the results with the most complete transition operator in the same color code. The experimental 68% CI for  $B(M1)$ (present work) is indicated by a shaded area, and the most probable values of  $B(M1)$  and  $\mu$  [\[3\]](#page-4-4) by a solid line (the CI of  $\mu$  is not visible at this scale).

theory are probably related to missing higher-order contributions to the  $M1$  operator. The increase of the  $B(M1)$ strength is also found in quantum Monte Carlo (QMC) calculations when  $2BC$  are included  $[11,12]$  (see also Table [I\)](#page-3-0).

In contrast to the data points that presently dominate the world average, this measurement was performed directly at the photon point and with controlled systematic uncertainties. In total, a relative uncertainty of 2% with balanced contributions by statistics and systematics was achieved. This translates into an uncertainty of about 2 attoseconds for the half-life of the  $0^+_1$  state of <sup>6</sup>Li. In addition,  $\chi$ EFT nuclear structure calculations were performed that take into account 2BC at NLO, combined with chiral interactions at various orders, for the first time. Excellent agreement between experiment and theory was found at a new level of precision in both areas.

We thank the crew of the Superconducting Darmstadt Linear Accelerator for providing excellent conditions for experimentation. This work was supported by the Deutsche Forschungsgemeinschaft (DFG) under Grant Nos. SFB 634 (Project ID 5485852), SFB 1044 (204404729), SFB 1245 (279384907) and the Cluster of Excellence  $PRISMA^{+}$  (39083149), by the Bundesministerium für Bildung und Forschung under Grant No. 05P18PKEN9, and by the State of Hesse within the LOEWE research project "Nuclear Photonics." Numerical calculations have been performed on the Lichtenberg cluster at the computing center of the TU Darmstadt. This material is based upon work supported by the U.S. Department of Energy, Office of Science, Office of Nuclear Physics, under the FRIB Theory Alliance Award No. DE-SC0013617. M. B., P. C. R., T. B., and U. F. G. acknowledge support by the Helmholtz Graduate School for Hadron and Ion Research of the Helmholtz Association. R. S. acknowledges support by the International Max Planck Research School for Precision Tests of Fundamental Symmetries.
