(Received 26 February 2021; revised 14 May 2021; accepted 24 August 2021; published 5 October 2021)

Sand dunes, which arise spontaneously due to the dynamical interplay between a sedimentary interface and a fluid flow, are one of the most famous examples of emergence in a geological system. The large scale organization of a dune field is believed to be controlled by pairwise (either remote or direct) dune-dune interactions. Recent studies have shown that remote long-range feedback is closely related to the turbulent wake structure forming downstream of a dune. Here, we study the stability of an idealized two-dune system arising as a consequence of such remote, wake-induced interactions. The system is realized in a subaqueous quasi-2D laboratory experiment and the results are compared with a qualitative dynamical systems model. Despite its simplicity, the system exhibits rich dynamical behavior. In particular, we show that, depending on the parameter regime, the dune-dune feedback can either stabilize or destabilize the symmetric dune configuration, and we demonstrate the existence of an asymmetric attracting state coupling dunes of different sizes.

DOI: [10.1103/PhysRevLett.127.154501](https://doi.org/10.1103/PhysRevLett.127.154501)

Sand dunes often form vast collectives known as dune fields [1–[3\],](#page-4-1) which continually evolve due to erosion and deposition induced by the flow of the overlaying fluid [\[4](#page-4-2)–8]. The migration of terrestrial dunes is related to desertification and poses a threat to human-made infrastructure, both in deserts and under water[\[5,9,10\].](#page-4-3) By studying extraterrestrial dunes we can also learn about the weather conditions on other planets [\[11,12\].](#page-4-4) Dune field modeling, therefore, is a pressing need, but it is also challenging as full resolution of all the relevant fluid dynamics is practically impossible with the current computational resources. Consequently, numerical studies typically rely on empirical parametrizations. The most radical reduced models abstract a sparse dune field as a population of discrete agents interacting with their surroundings. Previous models of this kind focused on collisional interactions leading to billiardlike dynamics [\[1,3,13](#page-4-1)–20]. However, recent experimental and observational studies revealed that dunes can also interact over sizable distances without necessarily directly colliding [\[21](#page-4-5)–25]. Therefore, while the agent-based models still remain attractive, their parametrization stands in need for a revision.

In this Letter, we study the stability of an experimentally realized quasi-2D two-dune system [26–[29\],](#page-4-6) which can be regarded as a paradigm of remote dune-dune interactions. In our experiments we use a narrow annular flume (see Fig. [1](#page-1-0)) which gives the unique opportunity to impose periodic boundary conditions in a laboratory experiment [\[24\]](#page-4-7) (for technical details see Supplemental Material [\[30\]](#page-5-0)). The closest natural analog of our experimental dunes are spanwise-invariant transverse dunes, but they can also be interpreted as streamwise transects of more complex bedforms [\[33\]](#page-5-1). Quasi-2D bedforms have received significant attention in the theoretical literature, which allows us to place our experimental results in the context of wellestablished theories [\[33,34\]](#page-5-1).

For quasi-2D dunes confined in a channel of width W, the changes in sediment topography  $h(x, t)$  can be related to the sand flux  $q(x, t)$  [MT<sup>-1</sup>] through the Exner equation  $\begin{bmatrix} 4 & 34 \end{bmatrix}$ [\[4,34\]](#page-4-2)

$$
\frac{\partial h}{\partial t} + \frac{1}{\rho} \frac{\partial q}{\partial x} = 0, \tag{1}
$$

where

$$
\rho = \rho_p \eta W \tag{2}
$$

is the effective density of the quasi-2D bedform,  $\rho_p$  is the actual sediment density, and  $\eta$  is the bed packing fraction. As a corollary, a steady-shape migrating dune moves at rate

$$
c = \frac{q^c - q^i}{\rho h^c},\tag{3}
$$

where  $q^i$  is the upstream sediment influx,  $q^c$  is the sediment flux at dune's crest, and  $h^c$  is the crest height [\[4,33,34\].](#page-4-2) If the dune's cross section remains self-similar in shape, we can also assume

$$
h^c = \sqrt{\frac{km}{\rho}},\tag{4}
$$

where  $m$  is the mass of the dune and  $k$  is a proportionality constant.

We shall now specialize to the problem of a two-dune system in a periodic domain. In a reduced model, this system is described by four variables  $(x_1, x_2, m_1, m_2)$  [\[35\]](#page-5-2), but we can reduce its dimensionality even further. First, due to rotational symmetry of the system, we will only focus on the relative dune separation

$$
\Delta x = x_2 - x_1. \tag{5}
$$

Second, we will assume that the interdune particle transit times are instantaneous, so the respective influxes and outfluxes are equal and

$$
m_2 = M - m_1,\t\t(6)
$$

<span id="page-1-2"></span>where  $M$  is the total mass of sediment in the flume. Thus, the state of our system is fully described by separation  $\Delta x$ and the mass  $m = m_1$  coupled by the following equations:

<span id="page-1-3"></span>
$$
\frac{d(\Delta x)}{dt} = \frac{q_2^c - q_1^o}{\sqrt{k\rho(M-m)}} - \frac{q_1^c - q_2^o}{\sqrt{k\rho m}},
$$
(7)

$$
\frac{dm}{dt} = q_2^o - q_1^o. \tag{8}
$$

<span id="page-1-1"></span>In order to parametrize the remote dune-dune interactions, we will assume that the respective fluxes are modulated by the upstream conditions, i.e.,

$$
q_1^c = q_0 \{ 1 + f^c [2\pi R - \Delta x, (M - m)/\rho] \},
$$
  
\n
$$
q_1^o = \epsilon q_0 \{ 1 + f^o [2\pi R - \Delta x, (M - m)/\rho] \},
$$
  
\n
$$
q_2^c = q_0 [1 + f^c(\Delta x, m/\rho)],
$$
  
\n
$$
q_2^o = \epsilon q_0 [1 + f^o(\Delta x, m/\rho)].
$$
\n(9)

Parameter  $\epsilon$  is the "sand trapping efficiency" [\[35,36\]](#page-5-2), quantifying how much of the sand swept away from one dune's crest is trapped by the flow recirculation in the lee [\[37](#page-5-3)–39]. Lacking exact experimental measurements, we shall refrain from suggesting any particular form for the interaction functions  $f^c$  and  $f^o$ . Nevertheless, based on previous experiments [\[24\]](#page-4-7) we can postulate three properties: (1)  $f^c, f^o \geq 0$ , as the turbulent fluctuations generically enhance sediment flux; (2)  $[(\partial f^c)/(\partial y_1)](y_1, y_2)$ ,<br> $[(\partial f^o)/(\partial y_1)](y_1, y_2) < 0$  as feedback is expected to decay  $[(\partial f^{\circ})/(\partial y_1)](y_1, y_2) \le 0$ , as feedback is expected to decay<br>away from the unstream dune: (3)  $[(\partial f^{\circ})/(\partial y_2)](y_1, y_2)$ away from the upstream dune; (3)  $[(\partial f^c)/(\partial y_2)](y_1, y_2)$ ,<br> $[(\partial f^o)/(\partial y_2)](y_1, y_2) > 0$  as feedback is expected to be  $[(\partial f^o)/(\partial y_2)](y_1, y_2) \ge 0$ , as feedback is expected to be<br>stronger for larger obstacles stronger for larger obstacles.

<span id="page-1-0"></span>

FIG. 1. (a) Experimental setup. Annular channel of outer radius  $R$  and a working section of width  $W$ , filled with water up to  $H_w = 45$  cm. The dominant flow, induced by paddle motion, is from the blue (upstream) dune to the red (downstream) dune. Paddle tip position  $H_p$ , as well as the table rotation rate  $\Omega_t$  and the paddle rotation rate  $\Omega_p$  vary between experiments (cf. Table [I\)](#page-2-0). (b) Quasi-2D two-dune problem with dunes of masses  $m_1 = m, m_2 = M - m$  and crests of height  $h_{1,2}^c$ , located at  $x_{1,2}$ .<br>The evolution of the system can be related to respective (edd) The evolution of the system can be related to respective (sediment) crest fluxes  $q_{1,2}^c$ , influxes  $q_{1,2}^i$ , and outfluxes  $q_{1,2}^o$ .

Expressions [\(9\)](#page-1-1) provide a closure for the system [\(7\)](#page-1-2) and [\(8\)](#page-1-3). For mathematical convenience, we shall now replace its dimensional variables with nondimensional

$$
\Delta \theta = \Delta x / R, \qquad \mu = m / M, \qquad \tau = t \frac{\Omega_{\text{tot}} R \rho d}{M}, \qquad (10)
$$

where d is the mean particle diameter and  $\Omega_{\text{tot}}R =$  $|\Omega_p - \Omega_r|$ R provides the velocity scale [cf. Fig. [1\(a\)\]](#page-1-0).

Note that  $(\Delta \theta, \mu) \in [0, 2\pi) \times [0, 1]$  and, due to periodic undary conditions, the system possesses a symmetric boundary conditions, the system possesses a symmetric fixed point  $S = (\Delta \theta = \pi, \mu = 1/2)$ . Its linear stability properties are (naturally) controlled by the eigenvalues of the Jacobian matrix J, but in 2D they can be inferred from the values of the trace and determinant of J, without detailed calculation of the eigenvalues themselves. In our system,

$$
\mathrm{Tr}J = a_0 + a_1 \epsilon,\tag{11}
$$

<span id="page-1-5"></span><span id="page-1-4"></span>and

$$
DetJ = b_1 \epsilon + b_2 \epsilon^2, \qquad (12)
$$

where  $a_0$ ,  $b_2 < 0$  and  $b_1 > 0$  (see Supplemental Material [\[30\]](#page-5-0)). For fixed  $a_i$  and  $b_i$ , Eqs. [\(11\)](#page-1-4) and [\(12\)](#page-1-5) parametrically define a parabola in the trace-determinant plane. Thus, as  $\epsilon$ increases, we expect the fixed point to change its linear character. In particular, for  $\epsilon \ll 1$ , S is a stable node and in

<span id="page-2-1"></span>

FIG. 2. Trace-determinant plane. Shadings represent the dimension of the stable manifold  $E<sup>s</sup>$  and the hashed region corresponds to oscillatory solutions. All else being fixed, as the sand-trapping efficiency  $\epsilon$  increases we trace a parabola. Hence, one possible bifurcation scenario, depicted by the solid black line, is stable node (a)  $\rightarrow$  stable focus (b)  $\rightarrow$  stable node  $\rightarrow$ saddle (c).

the limit  $\epsilon \to \infty$ , it becomes a saddle. In the intermediate regime, depending on the exact values of  $a_i$  and  $b_i$ , there is also a possibility of both damped and amplified oscillatory solutions (Fig. [2](#page-2-1)).

This simple analysis can be used to explain our experimental results, which show that the stability properties of S change as we vary the flow parameters. The relationship between the flow conditions and  $\epsilon$  can be understood in terms of the turbulence intensity  $\mathcal I$ . We should emphasise, however, that due to experimental limitations we cannot measure either  $\mathcal I$  or  $\epsilon$ , so our arguments remain purely qualitative. To begin with, recall that the sand trapping efficiency  $\epsilon$  can be interpreted as a ratio of fluxes  $\epsilon \sim q^{\circ}/q^{\epsilon}$ . As previously noted,  $q^{\circ}$  can be increased by the turbulent gusts, which allow single sand particles to bypass the recirculation region [\[24,40](#page-4-7)–42]. Therefore, it is plausible that  $q^o$ , and therefore  $\epsilon$  increases as  $\mathcal I$  increases. Indeed, even though the turbulent fluctuations can increase  $q<sup>c</sup>$  as well,  $q<sup>c</sup>$  does not critically rely on these fluctuations in the way the remote transport to the other dune (and hence  $q^o$ ) does. As far as the experiment is concerned,  $\mathcal I$  can be increased in at least two ways. First, it can be increased by increasing the net driving rotation rate  $\Omega_{\text{tot}} = |\Omega_p - \Omega_t|$  [i.e., the differential angular speed between the paddle and the turntable, see Fig. [1\(a\)\]](#page-1-0), which impacts the channel-based

<span id="page-2-0"></span>TABLE I. Experiments. Flow boundary conditions as well as the initial condition for the six experiments presented in this Letter. The counterrotation ratio  $|\Omega_p/\Omega_t|$  is tuned empirically to ensure a quasi-2D profile of the sedimentary bed [\[43\]](#page-5-4).

Experi- ment			$H_p$ (cm) $\Omega_{\text{tot}}$ (rpm) $\Omega_t$ (rpm) $\Omega_p$ (rpm) $\Delta\theta(0)$			$\mu(0)$
$\overline{1}$	38.5	13.5	$-5.10$	8.40	$\pi/4$	1/2
2	38.5	13.5	$-5.10$	8.40	π	4/11
3	34	13.5	$-5.40$	8.10	$\pi/4$	1/2
$\overline{4}$	34	13.5	$-5.40$	8.10	π	4/11
5	24	15.5	$-6.30$	9.20	π	1/2

Reynolds number. Second, it can be increased by reducing  $H_p$ , which is the distance between the channel's floor and lower tip of the paddle which sheds intense turbulent structures. If  $H_p$  is large, most of the eddies dissipate before they reach the floor, but if  $H_p$  is small, they impinge on the surface of a dune with more intensity. These two numbers ( $\Omega_{\text{tot}}$  and  $H_p$ ) are the only flow parameters which vary across the six experiments presented in this Letter and which are summarized in Table [I](#page-2-0). The experiments could last up to 80 h, so for technical reasons they had to be paused several times. However, through independent validation experiments, we are confident that stopping and restarting an experiment has no significant dynamical effect after a spinup time of the order of 60 s.

Experiments 1 and 2 [Fig. [3\(d\)](#page-3-0)] were conducted under the relatively quiescent, but still definitely turbulent (Re<sub>dune</sub> ~ 10<sup>4</sup>), flow conditions, with  $H_p = 38.5$  cm, so that the blade protrudes above the free surface. Experiment 1 corresponds to a pure  $\Delta\theta$  perturbation and experiment 2 started from a  $\mu$  perturbation away from the symmetric fixed point S. In both cases, the system eventually converges to S. Indeed, even though we cannot measure dune mass at all times without disrupting the experiment, it has been verified that the masses of the two dunes are virtually equal at the end of the experiment. Based on the character of the  $\Delta\theta$  time evolution, we conclude that under these flow conditions S behaves as a stable node, corresponding to the dynamical regime  $\epsilon \ll 1$ . The timescale separation  $({\frac{d\mu}{d\tau}}/{\frac{d(\Delta\theta)}{d\tau}} = O(\epsilon)$  is further corroborated<br>by the slow-fast characteristics apparent in experiment 2 by the slow-fast characteristics apparent in experiment 2. Here, we observe quick convergence toward the slow manifold (with  $\left\{ \frac{d(\Delta\theta)}{d\tau} \right\} \approx 0$ ) and a slow mass rearrangement.

As demonstrated in Fig.  $3(e)$ , the dynamics is qualitatively different when the paddle is lowered down further. This time, we observe manifest oscillations around S. Thus, at a linear level  $S$  acts as a focus (most likely stable), which would be consistent with intermediate values of  $\epsilon$ . Nevertheless, at the nonlinear level, the system exhibits very interesting excitable features. Indeed, experiment 4 demonstrates that the oscillations can be also spontaneously induced by the intrinsic system noise originating from turbulence and flume imperfections.

Finally, under the most turbulent conditions [Fig. [3\(f\)\]](#page-3-0), S becomes unstable. Here, the experiment was initiated exactly at S, but the system quickly moved away from the symmetric configuration and converged to an asymmetric attractor  $A \approx (\pi/2, 4/11)$ . The instability of S agrees with our linear stability analysis in the regime  $\epsilon = O(1)$ . Nevertheless, this calculation clearly cannot explain the existence of the asymmetric attractor A.

The nature of the asymmetric attractor A can be understood through consideration of the schematic shown in Fig. [4](#page-3-1). So far, our analysis has been based upon the implicit assumption that the domain length is small enough, so that

<span id="page-3-0"></span>

FIG. 3. Linear stability of the symmetric fixed point S. The top panels show illustrative theoretically predicted phase space diagrams for (a) a stable node, (b) a stable focus, (c) a saddle. The bottom panels show corresponding experimentally measured  $\Delta\theta(\tau)$ . (d) Under quiescent flow conditions S behaves as a stable node. The time course in magenta corresponds to a pure  $\Delta\theta$  perturbation and the time course in green was initialized with a pure  $\mu$  perturbation. (e) Under intermediately turbulent conditions the dynamics exhibits clear oscillatory features. (f) When the flow is sufficiently turbulent, the system diverges from the symmetric fixed point S and moves toward asymmetric attractor A.

the dune-dune feedback is bidirectional. This assumption is manifestly true for the symmetric fixed point  $S$ , but it may not be true for all the configurations. In particular, for sufficiently small  $\mu$ , there may be a range of dune separations  $\Delta\theta$  where the dunes are effectively decoupled (shown in white in Fig. [4\)](#page-3-1). If that is the case,  $[(d\mu)/(d\tau)]=0$ <br>and the migration rate depends only on the dune size, so and the migration rate depends only on the dune size, so that  $\left\{ \frac{d(\Delta\theta)}{dt} \right\} < 0$  for  $\mu < \frac{1}{2}$  and  $\left\{ \frac{d(\Delta\theta)}{dt} \right\} > 0$  for  $\mu > 1$ . On the other hand, in the double limit  $\Delta\theta \to 0$ . for  $\mu > \frac{1}{2}$ . On the other hand, in the double limit  $\Delta \theta \to 0$ ,  $\mu \rightarrow 1$  (or symmetrically  $\Delta \theta \rightarrow 2\pi$ ,  $\mu \rightarrow 0$ ), which corresponds to a small upstream dune "chasing" a big downstream dune, we expect a unidirectional feedback (shaded light gray in Fig. [4\)](#page-3-1). If the small dune imposes sufficiently strong

<span id="page-3-1"></span>

FIG. 4. Asymmetric attractor. Schematic of the phase space explaining the physical nature of the asymmetric attractor A indicating distinct regions of one-sided, two-sided, or no interaction. The red line corresponds to a thought experiment trajectory, which can be used to infer the existence of an attracting forward-invariant region.

repulsion to prevent a collision, over a long time scale, the bigger dune is drained of mass, so the system is attracted toward the two-sided interaction region (shaded dark gray in Fig. [4](#page-3-1)). Thus, by considering a bounding trajectory starting in one of the one-sided interaction regions (red in Fig. [4\)](#page-3-1), we conclude that the instability of S implies the existence of a forward-invariant region A, which by the Poincaré-Bendixson theorem contains a simple attractor [\[44\].](#page-5-5) Nevertheless, unless the details of

<span id="page-3-2"></span>

FIG. 5. Transition. (a) Time course  $\Delta\theta(\tau)$  of experiment 6 starting from a small finite-size perturbation of S, which is nonlinearly unstable. (b) Differential speed of individual dunes for the same experiment. (c) Migration speed of the leading dune [cf. Fig. [1\(b\)\]](#page-1-0). Different colors denote different time periods.

the slow manifold are resolved, it is not guaranteed that A possesses a linearly stable fixed point. Indeed, we observe the dynamics around A is rather noisy [Figs.  $3(f)$  and  $5(a)$ ]. These large amplitude fluctuations may be ascribed to the fact that the small dune is more sensitive to mass perturbations, but they may also hint about the possible lack of a single attracting fixed point.

Figure [5](#page-3-2) shows an experiment near the bifurcation point where  $S$  is marginally stable. It is important to appreciate that, due to slow transients, it is difficult to determine if  $S$  is indeed linearly stable at this particular point, but it is clear that it certainly is unstable to finite-size (yet still relatively small) perturbations. The experiment starts with a small perturbation, approximately in the direction of the slow manifold, and it first moves toward a metastable intermediate state I with  $\Delta\theta \approx 0.8\pi$ . It is plausibly related to some relatively short-lived (in parameter space) fixed point which is born when S looses stability. Nevertheless, the system eventually drifts away from I and converges to the asymmetric state A, where it remains for the last 350 nondimensional time units, i.e., about 40 h, of the experiment. Figure [5\(b\)](#page-3-2) shows the difference in the migration rate between the two dunes throughout the experiment. It is important to realize that the differential velocity is in fact rather small, in that the migration rates of the two dunes agree to at least two significant figures. Nevertheless, the small excess of speed of the upstream dune over time accumulates to a significant change in  $\Delta\theta$ . Figure [5\(c\)](#page-3-2) shows also that the equilibrium migration rate is faster in A than in S, which agrees with the expectation that the migration rate should be dictated by the smallest dune in the system.

Our experimental setup clearly lacks the complexity of any natural dune field, but the agent-based framework is sufficiently general to draw a robust analogy between our experiments and natural dunes. Thus, we would argue that these results form an essential first step toward understanding the role of remote dune-dune interactions by demonstrating how such interactions can qualitatively change the longtime coupled dynamics through a remote sand transport feedback. As we have seen, this feedback can have both stabilizing and destabilizing effects. Of particular interest is also the evidence of the existence of an asymmetric attracting state, where dunes of different sizes (and different downstream separations) couple in a balanced fashion over very long times. The next step is to consider the implications of this feedback for a longer train of dunes and the 3D phenomena, such as fragmentation [\[21,25,45,46\]](#page-4-5) or calving [\[18\]](#page-4-8).
