(Received 13 July 2021; accepted 19 January 2022; published 1 March 2022)

We have conducted fully relativistic simulations in a class of scalar-tensor theories with derivative selfinteractions and screening of local scales. By using high-resolution shock-capturing methods and a nonvanishing shift vector, we have managed to avoid issues plaguing similar attempts in the past. We have first confirmed recent results by ourselves in spherical symmetry, obtained with an approximate approach and pointing at a partial breakdown of the screening in black-hole collapse. Then, we considered the late inspiral and merger of binary neutron stars. We found that screening tends to suppress the (subdominant) dipole scalar emission, but not the (dominant) quadrupole scalar mode. Our results point at quadrupole scalar signals as large as (or even larger than) in Fierz-Jordan-Brans-Dicke theories with the same conformal coupling, for strong-coupling scales in the MeV range that we can simulate.

DOI: [10.1103/PhysRevLett.128.091103](https://doi.org/10.1103/PhysRevLett.128.091103)

The investigation of gravitational theories beyond General Relativity (GR) has recently intensified, boosted by the detection of gravitational waves (GWs) by LIGO and Virgo [\[1](#page-4-0)–[4](#page-4-1)], which allows for testing gravity in the hitherto unexplored strong-gravity and highly relativistic regime. Natural questions preliminary to these tests, however, are the following: Do we really need to modify GR? What are the open problems that GR cannot address and which we wish to (at least partially) solve with a different theory? Leaving aside quantum gravity completions of GR, whose modifications only become important at the Planck scale, GR cannot explain the late-time accelerated expansion of the Universe, unless one introduces a cosmological constant (with its associated problems) or a dark energy component. Therefore, an alternative gravity theory should provide  $~\sim$ O(1) effects on cosmological scales to improve upon GR.

However,  $\sim \mathcal{O}(1)$  effects on large (cosmological) scales typically imply also  $\sim \mathcal{O}(1)$  deviations from GR on local (e.g., solar-system [[5](#page-4-2)] and binary-pulsar [\[6](#page-4-3)–[8\]](#page-4-4)) scales, where GR is tested to within  $\leq \mathcal{O}(10^{-5})$ . To comply with these stringent constraints, an obvious possibility is that the additional gravitational polarizations (besides the tensor modes of GR) have sufficiently weak self-couplings and coupling with other fields, including matter. This is the case of, e.g., Fierz-Jordan-Brans-Dicke (FJBD) theory [\[9](#page-4-5)–[11](#page-4-6)]. In this way, however, their cosmological effects are lost, and the theory cannot provide an effective dark energy phenomenology. Less trivially, the nontensor gravitons may self-interact (via derivative operators) so strongly near matter sources that the "fifth" forces they mediate are locally suppressed. This is the idea behind kinetic (or k-mouflage) [\[12\]](#page-4-7) and Vainshtein [\[13\]](#page-4-8) screening.

Although screening mechanisms have been widely advocated to reconcile modifications of GR on cosmological scales with local tests (see, e.g., [[14](#page-4-9),[15](#page-4-10)] for reviews), their validity has never been proven beyond certain simplified approximations (single body [\[12\]](#page-4-7), weak gravity [\[16](#page-4-11)[,17\]](#page-4-12), quasistatic configurations [[18](#page-4-13)–[20](#page-4-14)], spherical symmetry [[21](#page-4-15)]), let alone in realistic compact-binary coalescences. Here, we will provide the first numerical-relativity simulations of compact binaries in theories with kinetic screening, and finally address the long-standing question of whether screening mechanisms render GW generation indistinguishable from GR.

Theories with kinetic screening, i.e., k-essence theories, are the most compelling modified-gravity candidate for dark energy after GW170817 [[22](#page-4-16),[23](#page-4-17)] and other constraints related to GW propagation [\[24](#page-4-18)–[26](#page-4-19)]. In the Einstein frame [\[27\]](#page-4-20), the action of this scalar-tensor theory is [\[28](#page-4-21)[,29\]](#page-4-22)

$$
S = \int d^4x \sqrt{-\tilde{g}} \left[ \frac{M_{\rm Pl}^2}{2} \tilde{R} + K(\tilde{X}) \right] + S_m \left[ \frac{\tilde{g}_{\mu\nu}}{\Phi(\phi)}, \Psi_m \right], \quad (1)
$$

<span id="page-0-0"></span>where  $\tilde{X} \equiv \tilde{g}^{\mu\nu} \partial_{\mu} \phi \partial_{\nu} \phi$ ,  $\Psi_m$  are the matter fields,  $\Phi = \exp(\sqrt{2\alpha}\phi/M_{\text{Pl}})$ , being  $M_{\text{Pl}} = (8\pi G)^{-1/2}$  the Planck mass, and we set  $\hbar = c = 1$ . For  $K(\tilde{X})$ , we only consider the lowest-order terms

<span id="page-1-0"></span>

FIG. 1. Top: Central scalar field for rotating and nonrotating stars produced with our three-dimensional code and nonrotating ones produced with the static one-dimensional code of [\[41](#page-4-31)]. Stellar masses are  $M \approx 1.74$  M<sub>o</sub>. Also shown is the expected linear scaling with Λ [\[42\]](#page-4-28). Bottom: Scalar field at the extraction radius for gravitational collapse (with mass  $M \approx 1.74 \text{ M}_{\odot}$ ), obtained with the one-dimensional code of [\[42\]](#page-4-28) (using an approximate fixingequation approach) and our three-dimensional code.

$$
K(\tilde{X}) = -\frac{1}{2}\tilde{X} + \frac{\beta}{4\Lambda^4}\tilde{X}^2 - \frac{\gamma}{8\Lambda^8}\tilde{X}^3 + ..., \qquad (2)
$$

where  $\Lambda$  is the strong-coupling scale of the effective field theory. For the scalar to be responsible for dark energy, one needs  $\Lambda_{\text{DE}} \sim (H_0 M_{\text{Pl}})^{1/2} \sim 2 \times 10^{-3}$  eV, where  $H_0$  is the present Hubble rate. The conformal coupling  $\alpha$  and the coefficients  $\beta$  and  $\gamma$  appearing in Eq. [\(2\)](#page-0-0) are dimensionless and  $~\sim \mathcal{O}(1)$ .

Performing neutron-star (NS) numerical-relativity simulations in k-essence is complicated by the strong-coupling nature of the scalar self-interactions [\[30\]](#page-4-23). Although the Cauchy problem is locally well-posed, the evolution equations may change character from hyperbolic to parabolic and then elliptic at finite time [\[35,](#page-4-24)[36\]](#page-4-25). This behavior can be avoided by imposing "stability" conditions on the coefficients  $\beta$ ,  $\gamma$ , ... of Eq. [\(2\)](#page-0-0) [[36\]](#page-4-25), just like other conditions (e.g., no ghosts, tachyons, or gradient instabilities) are usually imposed on the coefficients of any effective field theory [[37](#page-4-26)]. Nevertheless, even under these stability conditions, the characteristic speeds of the scalar field are found to diverge during gravitational collapse [\[35](#page-4-24)[,36](#page-4-25)[,40](#page-4-27)–[42](#page-4-28)]. This may be physically pathological, and it is certainly a serious practical drawback, as the Courant–Friedrichs–Lewy condition [\[43](#page-4-29)] forbids to evolve the fully nonlinear dynamics past this divergence. Recently, [\[42\]](#page-4-28) managed to evolve gravitational collapse past the scalar-speed divergence by slightly modifying the dynamics, with the addition of an extra driver field [\[44](#page-4-30)–[46\]](#page-5-0). This technique, while *ad hoc* and approximate, suggests that the divergence is not of physical origin, but rather linked to the gauge choice, as conjectured in [\[36\]](#page-4-25). In this Letter, we use indeed a gauge choice (including a nonvanishing shift) that maintains the characteristic speeds finite during both gravitational collapse and binary evolutions in  $3 + 1$  dimensions. The latter constitute the first fully dynamical simulations of the GW generation by binary systems in theories with screening.

Setup.—In order to perform fully relativistic numerical simulations of binary mergers in  $k$ -essence theory, we consider the Einstein frame and evolve the CCZ4 formulation [\[47](#page-5-1)–[49](#page-5-2)] of the Einstein equations (with the 1+log slicing [[50](#page-5-3)] and the Gamma-driver shift condition [[51](#page-5-4)]) coupled to a perfect fluid (adopting an ideal-gas equation of state with  $\Gamma = 2$ ) [\[52](#page-5-5)] and a scalar field [\[53\]](#page-5-6). Without loss of generality, we fix  $\beta = 0$  and  $\gamma = 1$ , which ensure the wellposedness of the Cauchy problem [\[36](#page-4-25)] and the existence of screening solutions [\[41,](#page-4-31)[42](#page-4-28)] [\[54\]](#page-5-7). Furthermore, we set the conformal coupling to  $\alpha \approx 0.14$ . As discussed in [[42](#page-4-28)],  $\Lambda \sim$  $\Lambda_{\text{DE}}$  is intractable numerically due to the hierarchy between binary and cosmological scales (which leads to  $\Lambda_{DE} \sim 10^{-12}$ in units adapted to the binary system). Like in [\[41](#page-4-31)[,42\]](#page-4-28), we study  $\Lambda \gtrsim 1$  MeV (for which screening is already present).

The computational code, generated by using the platform SIMFLOWNY [\[57](#page-5-8)–[59](#page-5-9)], runs under the SAMRAI infrastructure [\[60](#page-5-10)–[62](#page-5-11)], which provides parallelization and the adaptive mesh refinement required to solve the different scales in the problem. We use fourth-order finite difference operators to discretize our equations [\[48](#page-5-12)]. For the fluid and the scalar, we use high-resolution shock-capturing (HRSC) methods to deal with shocks, as discussed in [[36](#page-4-25)[,41](#page-4-31)[,42\]](#page-4-28). A similar GR code, using the same methods, has been recently used to simulate binary NSs [[52](#page-5-5),[63](#page-5-13)]. Our computational domain ranges from  $[-1500, 1500]^3$  km and contains 6 refinement levels. Each level has twice the resolution of the previous one, achieving a resolution of  $\Delta x_6 = 300$  m on the finest grid. We use a Courant factor  $\lambda_c \equiv \Delta t_l / \Delta x_l = 0.4$  on each refinement level  $l$  to ensure stability of the numerical scheme. Full details, together with convergence tests, are provided in the Supplemental Material [[64\]](#page-5-14).

Isolated stars and gravitational collapse.—We construct initial data for NS systems in  $k$ -essence theory by relaxation [\[66](#page-5-15)[,67\]](#page-5-16), i.e., we generate GR solutions using LORENE [\[68\]](#page-5-17) and evolve them in k-essence until that they relax to

<span id="page-2-0"></span>

FIG. 2. Unequal-mass ( $q = 0.91$ ) NS binary with  $\Lambda = 4.0$  MeV, shown at successive times. The color code represents the scalar field, which is initially centered on each star and then develops into a common "envelope," while the dark orange represents the fluid density.

stationary solutions. These solutions agree with the nonrotating solutions for k-mouflage stars found in [\[41,](#page-4-31)[42](#page-4-28)], thus validating our relaxation technique (Fig. [1](#page-1-0), top panel). Similarly, we have also considered rotating solutions in k-essence, finding for the first time that (i) they behave qualitatively like the nonspinning ones, and (ii) the screening mechanism also survives in axisymmetry (Fig. [1](#page-1-0), top panel). We also reproduced the dynamics of stellar oscillations in *k*-essence found in  $[41, 42]$  $[41, 42]$  $[41, 42]$  $[41, 42]$  $[41, 42]$ , and managed to follow the (spherical) black-hole collapse of a NS (Fig. [1](#page-1-0), bottom panel). These simulations were inaccessible, due to the diverging characteristic speeds, within the framework of [\[41\]](#page-4-31), without the addition of an extra driver field and a "fixing equation" [[44](#page-4-30),[45](#page-4-32)] for it [[42](#page-4-28)]. Here, using the gauge conditions mentioned above (and typically employed in numerical-relativity simulations of compact objects in  $3 + 1$ dimensions), we found no divergence of the characteristic speeds in our class of k-essence theories. The collapse obtained with this gauge matches exactly the results obtained in [\[42\]](#page-4-28), as shown in the bottom panel of Fig. [1](#page-1-0), corroborating the (approximate) "fixing-equation" technique employed there. We will therefore use the aforementioned gauge conditions throughout this Letter.

Binary evolutions.—Like in the isolated case, initial data for binary systems are constructed by relaxation. The relaxation process occurs approximately in the initial 4 ms of our simulations, and does not impact significantly the subsequent binary evolution. We consider binary NSs in quasicircular orbits with a total gravitational mass 2.8–2.9 M<sub>o</sub> and mass ratio  $q = M_2/M_1 = [0.72, 1].$ Time snapshots of a binary with mass ratio  $q = 0.9$  in a theory with  $\Lambda \approx 4$  MeV are shown in Fig. [2,](#page-2-0) displaying both the star's density and the scalar field. The screening radii of the stars in isolation are ∼120 km and thus larger than the initial system separation. This is the physically relevant situation, as for  $\Lambda \sim \Lambda_{DE}$  the screening radii are  $\sim 10^{11}$  km. Also observe the formation of a scalar wake trailing each star (for the most part), with the two wakes merging in the last stages of the inspiral.

The response of a detector to the GW signal from NS binaries is encoded in the Newman-Penrose invariants in the Jordan frame [\[69](#page-5-18)], i.e., projections of the Riemann

<span id="page-2-1"></span>

FIG. 3. Tensor  $(l = m = 2)$  and scalar  $(l = m = 1$  and  $l = m = 2)$  strain for a NS merger with  $q = 0.91$ , in k-essence and FJBD.

<span id="page-3-0"></span>

FIG. 4. Dipole  $(l = m = 1)$  and quadrupole  $(l = m = 2)$  scalar strain for merging NS binaries of varying mass ratio, in k-essence and FJBD.

tensor on a null tetrad  $l, n, m, \bar{m}$  adapted to outgoing waves. Tensor and scalar GWs are encoded respectively in  $\psi_4 = -R_{\ell \bar{m} \ell \bar{m}} = \Phi \tilde{\psi}_4$  and in  $\phi_{22} = -R_{lml\bar{m}} =$  $\phi(\tilde{\phi}_{22} - l^{\nu} l^{\mu} \nabla_{\nu} \nabla_{\mu} \log \Phi/2 + \cdots)$ , with a tilde denoting quantities in the Einstein frame (where we perform our simulation) and the dots denoting terms subleading in the distance r. We place our extraction radius outside the screening radius of the individual NSs, at distances of 300 km from the center of mass. This is justified because the distance to the detector is typically  $\gg 10^{11}$  km, which is the screening radius for  $\Lambda \sim \Lambda_{\rm DE}$ , even for Galactic sources. In this regime, the amplitude of scalar perturbations decays as  $1/r$ , and therefore  $\phi_{22} \approx -\alpha \sqrt{16\pi G} \partial_1^2 \phi$  +  $O(1/r^2)$  [\[42,](#page-4-28)[66](#page-5-15)].

The tensor and scalar "strains," h and  $h_s$ , are defined by integrating  $\psi_4$  and  $\phi_{22}$  twice in time, i.e.,  $\psi_4 = \partial_t^2 h/2$  and  $\phi_{22} = \partial_t^2 h_s$ . The latter definition yields simply  $h_s \propto \phi$  [[70](#page-5-19)]. We then decompose h and  $h<sub>s</sub>$  (or  $\phi$ ) into spin-weighted spherical harmonics. As expected, the dominant contribution comes from the  $l = m = 2$  mode for the tensor strain. For the scalar emission the monopole  $l = m = 0$  is suppressed, and the main contribution comes from the dipole  $(\ell = m = 1)$  mode and (mostly) the quadrupole  $l = m = 2$ ) mode. The results for four simulations—for  $\Lambda \approx 4$ , 5, and 7 MeV and for FJBD (corresponding to  $\Lambda \rightarrow \infty$ ), with  $\alpha \approx 0.14$ —are shown in Fig. [3.](#page-2-1) Notice that we do not show the GR tensor strain as it is practically indistinguishable from the FJBD one on this timescale [[66](#page-5-15)]. The three values of  $\Lambda$  predict screening radii larger than the initial separation between the stars.

As can be seen, the tensor strains are very similar, even after the merger (corresponding to the peak amplitude). As for the scalar, the suppression of the  $l = m = 0$  mode is expected, since monopole emission vanishes in FJBD theory for quasicircular binaries [[71](#page-5-20),[72\]](#page-5-21). The  $l = m = 1$  dipole mode is instead small but nonvanishing, as expected for unequal-mass binaries in FJBD, with signs of screening suppression as  $\Lambda$  decreases. However, the (dominant)  $l = m = 2$  scalar quadrupole mode is always *larger* than in FJBD theory, suggesting that the screening is not effective at suppressing the quadrupole scalar emission in the late inspiral and merger. The amplitude also seems to increase when going to low frequencies (early times), in the simulations with  $\Lambda \approx 4$  and 5 MeV. Note that one does not expect a continuous limit to FJBD ( $\Lambda \rightarrow \infty$ ) when  $\Lambda$  increases. In FJBD there is no screening and the binary is always in the perturbative regime, while in k-essence the separation is always smaller than the screening radii. This is true even for observed binary pulsars, which have separations  $\lesssim\!10^5\,$  km vs screening radii of ~10<sup>11</sup> km for  $\Lambda \sim \Lambda_{\text{DE}}$ .

The dependence on the mass ratio of the binary (which we set to  $q = 1, 0.9$  and 0.71) is shown in Fig. [4,](#page-3-0) for the FJBD and  $\Lambda \approx 4$  MeV cases. As can be observed, quadrupole fluxes are largely unaffected by  $q$  in both theories, with the k-essence ones consistently larger, especially at early times. The dipole fluxes in *k*-essence show again signs of suppression relative to FJBD, at least for  $q \neq 1$ , but in both theories they grow as  $q$  decreases. This is expected, since post-Newtonian calculations in FJBD [[71](#page-5-20),[72](#page-5-21)] predict that the dipole amplitude should scale as the difference of the stellar scalar charges, which grows as  $q$  decreases. For  $q = 1$ , instead, the dipole flux in FJBD is compatible with zero (as predicted by post-Newtonian theory [\[71,](#page-5-20)[72\]](#page-5-21)), while it does *not* vanish in *k*-essence.

Conclusions.—We have performed for the first time fully relativistic simulations of binary NSs in theories of gravity with kinetic screening of local scales. We dealt with shocks in the scalar field by a HRSC method and by adopting a gauge with nonzero shift that prevents divergences of the characteristic speeds, which plagued previous attempts [\[35](#page-4-24)[,36,](#page-4-25)[41](#page-4-31)]. With this setup, we have confirmed previous preliminary results by ourselves [\[42\]](#page-4-28), which were obtained with an approximate fixing-equation approach [\[44,](#page-4-30)[45\]](#page-4-32) and which hinted at a possible breakdown of the screening in black-hole collapse. In the late inspiral and merger of binary NSs, the (subdominant) dipole scalar emission is screened (at least for unequal masses), but the (dominant) quadrupole scalar flux is not. In fact, our results seem to hint at quadrupole scalar emission being as important (or even larger, especially at low frequencies) in k-essence than in FJBD theories with the same conformal coupling  $\alpha$ , as long as the strong-coupling scale is in the MeV range that we can simulate. If this feature survives for  $\Lambda \sim \Lambda_{DE}$ , k-essence theories may become as fine-tuned as FJBD theory (which will wash out any effect on large-scale structure observations). Considering for instance the relativistic double-pulsar system J0737-3039 [[7](#page-4-33),[73](#page-5-22),[74](#page-5-23)], in FJBD the absence of scalar quadrupole radiation constrains  $|\alpha| \leq 4.4 \times 10^{-2}$ .

- <span id="page-4-23"></span>[30] For binary black holes, instead, no deviations from GR are expected, since the scalar equation's source  $(\alpha \alpha T)$  vanishes. This is also the reason behind the "no-hair" theorem for isolated black holes in  $k$ -essence [\[31\]](#page-4-34). The only deviations from GR in vacuum and in absence of a scalar mass [\[32\]](#page-4-35) may occur because of nontrivial initial conditions (which lead to transient scalar effects [[33](#page-4-36)]) and time-dependent boundary conditions for  $\phi$  [[34\]](#page-4-37).
