Parametric resonances and amplification have led to extraordinary photoinduced phenomena in pump-probe experiments. While these phenomena manifest themselves in out-of-equilibrium settings, here, we present the striking result of parametric amplification in equilibrium. We demonstrate that quantum and thermal fluctuations of a Raman-active mode amplifies light inside a cavity, at equilibrium, when the Raman mode frequency is twice the cavity mode frequency. This noise-driven amplification leads to the creation of an unusual parametric Raman polariton, intertwining the Raman mode with cavity squeezing fluctuations, with smoking gun signatures in Raman spectroscopy. In the resonant regime, we show the emergence of not only quantum light amplification but also localization and static shift of the Raman mode. Apart from the fundamental interest of equilibrium parametric amplification, our Letter suggests a resonant mechanism for controlling Raman modes and thus matter properties by cavity fluctuations. We conclude by outlining how to compute the Raman-cavity coupling, and suggest possible experimental realizations.

DOI: 10.1103/PhysRevLett.133.116901

**Introduction**—Driving condensed matter with light provides a methodology of controlling its properties in a dynamic fashion, in contrast to the established, static methods, as reflected in recent scientific studies [1–4]. In this effort, driving matter with laser light has proved to be a remarkably versatile tool in engineering properties of quantum materials such as controlling ferro-electricity [5], magnetism [6–9], superconductivity [10–15], topological features [16], and charge ordering [17,18]. Even more interestingly, driving with light has provided the possibility to create novel nonequilibrium states. A notable example includes photonic time crystals [19–23], materials that can function as parametric amplifiers for light. Another example is time crystals, denoting a robust, collective dynamical many-body state, in which the response of observables oscillates subharmonically [24–32].

The conceptual approach of dynamical control with light can be extended to the equilibrium domain through cavity-matter hybrids, see, e.g., [33–35]. This advancement of control via light involves replacing laser driving by quantum light fluctuations which are strongly coupled to matter through cavities [36], plasmonic resonators [37], surfaces hosting surface phonon polaritons [38,39], and photonic crystals [40]. The feasibility of this approach has been demonstrated experimentally, with examples including manipulation of transport [41], control of superconducting

properties [42], magnetism [43], topological features [37], cavity control of chemical reactivity [44–46], and cavity-enhanced spectroscopy [47–50].

In this Letter, we demonstrate that quantum and thermal noise of a Raman-active mode, can amplify cavity fluctuations in equilibrium. We emphasize that parametric amplification generally occurs in driven systems while here we present it in the context of an equilibrium amplification process. This amplification can in turn be used to resonantly control properties of matter and constitutes a novel method of light control, for Raman-cavity systems.

Our starting point is the nonlinear coupling between Raman active collective modes and light. Here Raman-active modes could be Raman phonons [51–53], molecular vibrations [13], Higgs modes in superconductors [54–56], and amplitude modes in charge density waves [18] that are even under inversion symmetry, and the electric field of a local cavity mode [57]. Therefore, at leading order, the Raman-light Hamiltonian reads  $H_{\text{Raman light}} = \lambda Q E_{\text{cav}}^2$  where  $E_{\text{cav}}$  is the electric field in the cavity,  $Q$  is the coordinate of the Raman mode and  $\lambda$  is the light-matter coupling. This quadratic coupling includes parametrically resonant processes of the type  $\hat{a}^\dagger \hat{a}^\dagger \hat{b} + \hat{a} \hat{a}^\dagger \hat{b}^\dagger$ , where  $\hat{a}$  and  $\hat{b}$  are the photon and Raman annihilation operators, respectively. In the presence of coherent Raman oscillations,  $\langle b(t) \rangle = A_0 e^{i\omega_R t}$ , at the Raman frequency  $\omega_R$ , the above coupling leads to exponential growth of the light field when the cavity frequency  $\omega_c$  satisfies the parametric resonant condition,  $2\omega_c = \omega_R$ . This observation naturally

leads to the question: can a randomly fluctuating field coming from Raman quantum fluctuations also amplify light? We find that the answer is yes which we demonstrate below.

To study this phenomenon, we use an open truncated-Wigner approximation method (open TWA) [58–60] to simulate the semiclassical dynamics of the Raman-cavity hybrids in the quantum fluctuation regime. We also determine the signatures of equilibrium parametric amplification using Raman spectroscopy [Fig. 1(a)]. We find that a prominent feature of parametric resonance and equilibrium light amplification is the appearance of two Raman polariton branches as shown in Fig. 1(b). We call this polariton parametric Raman polariton and its formation is attributed to the *nonlinear* process of mixing *squeezed photon fluctuations* with the Raman coordinate. This is substantially different to the existent polariton panorama where polaritons typically arise from a *linear* coupling between matter degrees of freedom and light [61]. To quantify the coupling between the Raman mode and the cavity, we compute the resonance splitting between the upper and lower parametric Raman polariton. This is a nonlinear extension of the usual Rabi splitting in the case of infrared active phonon polaritons [36]. We use a Gaussian theory to provide an analytical expression for this splitting

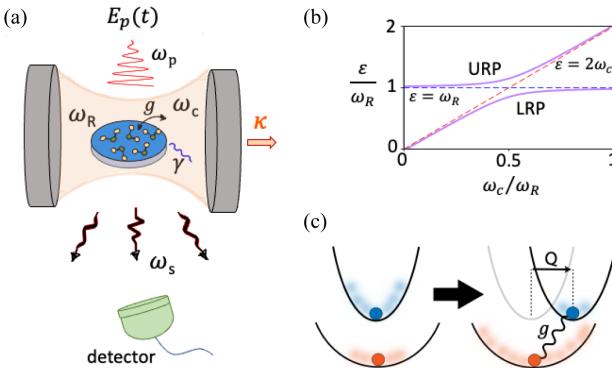

FIG. 1. Parametric Raman polaritons. (a) Sketch of a Raman medium (blue) coupled to a single cavity mode of frequency  $\omega_c$  (light-red shading) with a constant coupling  $g$ . Light can leak out of the cavity at a total decay rate  $\kappa$  while  $\gamma$  represents the damping associated with the Raman mode  $\omega_R$ . The wavy lines at the top and bottom represent a Raman spectroscopy scheme in which a probe field  $E_p(t)$  of frequency  $\omega_p$  is sent into the sample, and a detector (in green) collects the scattered photons at different frequencies  $\omega_s$  giving information about the hybrid Raman-cavity system. (b) Representative Raman spectrum (in purple) in which an avoided crossing appears at the resonant condition  $\omega_R = 2\omega_c$  indicating the existence of two branches, the upper (URP) and lower (LRP) Raman polaritons. (c) Sketch of how Raman (blue) and cavity (red) properties are modified due to the coupling  $g$ . Full circles represent the equilibrium position and shaded regions indicate fluctuations. In the resonant regime the cavity fluctuations are amplified while the Raman mode is statically shifted and localized, i.e., its fluctuations decrease.

as a function of the coupling strength which agrees well with the simulations.

The key features of the parametric Raman polariton are as follows: (i) The vacuum fluctuations of the cavity mode are amplified. (ii) The fluctuations of the Raman are reduced, in response to the amplification of the cavity fluctuations. This corresponds to a localization of the Raman mode. (iii) The average position of the Raman mode is statically shifted due to the cavity fluctuations as shown schematically in Fig. 1(c). These observations suggest that this mechanism can be used to resonantly modify and control both the Raman mode and the cavity in equilibrium. Furthermore, we conclude by proposing realistic experimental set-ups where this phenomenon can be observed.

*Raman-cavity model and Raman spectroscopy*—We consider a model, in which cavity field fluctuations are locally coupled to a Raman coordinate. The Hamiltonian for this system is given by

$$\frac{H}{\hbar} = \omega_c \hat{a}^\dagger \hat{a} + \omega_R \hat{b}^\dagger \hat{b} + g(\hat{b}^\dagger + \hat{b})(\hat{a}^\dagger + \hat{a})^2 + \frac{g_4}{4} (\hat{a}^\dagger + \hat{a})^4. \quad (1)$$

The cavity creation (annihilation) operator is  $\hat{a}^\dagger$  ( $\hat{a}$ ) and  $\omega_c$  is the cavity frequency.  $\hat{b}^\dagger$  and  $\hat{b}$  are the creation and annihilation operators for the Raman mode of frequency  $\omega_R$  and  $g$  is the coupling strength between the cavity and Raman mode. To connect these operators to the electric field in the cavity we require that  $\hat{E}_{\text{cav}}^2 = E_0^2(\hat{a} + \hat{a}^\dagger)^2$ , where  $E_0^2$  is the nonzero quantum noise of the electric field in the cavity that can be measured experimentally [37], while the cavity itself is in equilibrium,  $\langle \hat{E}_{\text{cav}} \rangle = 0$  and the Raman coordinate is given by  $\hat{Q} = [(\hat{b}^\dagger + \hat{b})/\sqrt{2\omega_R}]$ . The last term of strength  $g_4$  is an  $\hat{E}_{\text{cav}}^4$  type of nonlinearity necessary to make the system stable for finite coupling  $g < \sqrt{g_4 \omega_R}/2$ , a condition that is found analytically in Ref. [62].

We propose Raman spectroscopy as a natural probe for Raman polaritons. The spectroscopic protocol consists of an incoming probe laser of frequency  $\omega_p$  that can be scattered to free space as outgoing photons with frequency  $\omega_s$  after interacting with the Raman medium through a stimulated Raman scattering (SRS) [see Fig. 1(a)].

The probe is assumed to be a coherent light-source with an associated electric field  $E_p(t) = E_p^0 \sin(\omega_p t)$  whereas the scattered photons are described by the Hamiltonian  $H_s/\hbar = \omega_s \hat{a}_s^\dagger \hat{a}_s$ . The SRS Hamiltonian can be written as

$$\frac{H_p}{\hbar} = g_s E_p(t)(\hat{b}^\dagger + \hat{b})(\hat{a}_s^\dagger + \hat{a}_s), \quad (2)$$

where  $\hat{a}_s^\dagger$  ( $\hat{a}_s$ ) is the creation (annihilation) operator for scattered photons and  $g_s$  the coupling between the Raman

mode and photons being scattered. The requirement for weak probing is that  $g_s E_p^0$  is much smaller than  $g$ , as we will choose in the following.

Considering the total Hamiltonian  $H_t = H + H_p + H_s$  we derive the corresponding Heisenberg-Langevin equations of motion and use the open TWA method to solve the dynamics. This semiclassical phase-space method captures the lowest order quantum effects beyond mean-field treatment as demonstrated in different contexts [58–60,67] and consists of sampling the initial states from the corresponding Wigner distribution to take into account the quantum uncertainty. The equations of motion for the complex fields  $a$ ,  $b$ , and  $a_s$  associated with cavity, Raman motion and scattered photons operators are given by

$$\begin{aligned} i\partial_t a &= \omega_c a + 2g(a + a^*)(b + b^*) + g_4(a + a^*)^3 \\ &\quad - i\kappa a + i\xi_a, \end{aligned} \quad (3)$$

$$\begin{aligned} i\partial_t b &= \omega_R b + g(a + a^*)^2 + g_s E_p(t)(a_s + a_s^*) \\ &\quad - i\gamma(b - b^*)/2 - \xi_b, \end{aligned} \quad (4)$$

$$i\partial_t a_s = \omega_s a_s + g_s E_p(t)(b + b^*) - i\kappa_s a_s + i\xi_s. \quad (5)$$

Here  $\kappa$ ,  $\gamma$  and  $\kappa_s$  are the decay rates associated with the cavity, Raman and scattered photon field while  $\xi_a$ ,  $\xi_b$ , and  $\xi_s$  are sources of Gaussian noise obeying the autocorrelation relations  $\langle \xi_a^*(t_1)\xi_a(t_2) \rangle = \kappa\delta(t_1 - t_2)$ ,  $\langle \xi_b(t_1)\xi_b(t_2) \rangle = \gamma\delta(t_1 - t_2)$ , and  $\langle \xi_s^*(t_1)\xi_s(t_2) \rangle = \kappa_s\delta(t_1 - t_2)$ .  $\xi_a$  and  $\xi_s$  are complex valued whereas  $\xi_b$  is real-valued and, along with the damping term, enters only in the equation of motion for the imaginary part of the Raman field which is associated with the momentum of the Raman mode. The choice for the Raman mode is motivated by the Brownian motion in which the frictional force is proportional to the velocity.

We simulate the quantum Langevin Eqs. (3)–(5) using a stochastic ordinary differential equation solver and compute relevant observables in the steady state. To initiate the dynamics we ramp out  $g$  from zero to a finite value and wait for the steady state before turning on the probe field  $E_p(t)$ . In particular, we define the Raman spectrum as the number of scattered photons  $n_s = |a_s|^2$  as a function of their frequencies which is computed after a certain time of exposure to the probe field [62].

*Parametric Raman polaritons*—In Fig. 2(a) we show the Raman spectra  $n_s(\omega)$  for different cavity frequencies and a fixed  $g$  where  $\omega = \omega_p - \omega_s$  is the Raman shift. Away from resonance we see only one peak at  $\omega \approx \omega_R$ , which corresponds to the Stokes peak [68,69] of the Raman mode [70]. Near the resonance at  $\omega_c = \omega_R/2$  a second peak appears showing an avoided crossing, which signals the existence of a Raman polariton. To gain insight into the two polariton branches found numerically using the TWA method, we employ a Gaussian approximation [62]. Within this method, we find that the two polariton branches arise from

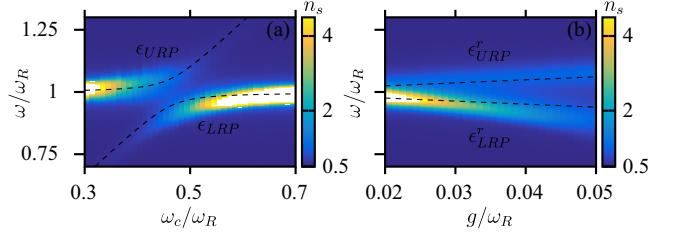

FIG. 2. (a) Raman spectra  $n_s(\omega)$  for different cavity frequencies  $\omega_c$ . We consider a probe laser of strength  $g_s E_p^0 = 0.04\omega_R$  and frequency  $\omega_p = 5\omega_R$  with  $g = 0.04\omega_R$ ,  $g_4 = \kappa = \gamma = \kappa_s = 0.01\omega_R$ . (b) Raman polariton branches at resonance ( $\bar{\omega}_c = \omega_R/2$ ) as a function of the coupling  $g$ . In both panels, the dashed black lines correspond to an analytical solution using a Gaussian approximation theory.

resonant coupling between the Raman mode oscillating at  $\omega_R$  and Gaussian squeezing oscillations of the photon, oscillating at  $2\omega_c$  leading to a new Raman polariton. We have computed analytically the dispersion of the lower and upper Raman polariton branches which are plotted with black dashed lines in Fig. 2(a), showing good agreement with the two numerical peaks in the Raman spectrum (indicated by  $\epsilon_{LRP}$  and  $\epsilon_{URP}$ ). The exact position of the avoided crossing is shifted to the left compared to the condition  $\omega_c = \omega_R/2$ , due to the renormalization of the cavity frequency by nonlinear interactions. Within the Gaussian approximation the effective cavity frequency is found to be  $\bar{\omega}_c = \omega_c - 12g^2/\omega_R + 3g_4$  so the improved estimate of the resonance condition is  $\bar{\omega}_c = \omega_R/2$ .

To quantify the strength of the Raman-cavity coupling, we define the Raman Rabi splitting as the difference between the upper and lower Raman polaritons on resonance,  $2\delta = \epsilon_{URP}(\bar{\omega}_c = \omega_R/2) - \epsilon_{LRP}(\bar{\omega}_c = \omega_R/2)$ . In Fig. 2(b) we plot the dependence of the Raman polariton branches on resonance  $\epsilon_{URP}^r = \epsilon_{URP}(\bar{\omega}_c = \omega_R/2)$  and  $\epsilon_{LRP}^r = \epsilon_{LRP}(\bar{\omega}_c = \omega_R/2)$  on the coupling strength  $g$ , and overlay the analytical prediction. The Rabi splitting grows linearly with  $g$  and is given by the expression

$$\delta = \sqrt{2\langle \hat{x}^2 \rangle \omega_R} (1 - 27g_4 \langle \hat{x}^2 \rangle^3 / 2)g + \mathcal{O}(g^3). \quad (6)$$

Interestingly, the Gaussian theory suggests that the Rabi splitting could be parametrically enhanced by the cavity quantum fluctuations  $\langle \hat{x}^2 \rangle$ , where  $\hat{x} = [(a + a^\dagger)/\sqrt{2\omega_c}]$ . Perturbatively,  $\langle \hat{x}^2 \rangle = (1/2\omega_c) + \mathcal{O}(g^2)$ , which is the value we use in Eq. (6) to plot the dashed lines in Fig. 2(b).

*Equilibrium parametric amplification*—While Raman spectroscopy provides experimental evidence for strong Raman-cavity coupling, we now expand the discussion to the equilibrium properties of the Raman polariton which exhibit equilibrium parametric amplification. This phenomenology corresponds to the amplification of photon fluctuations accompanied by a localization of Raman mode

fluctuations, i.e., suppression of fluctuations, depicted schematically in Fig. 1(c).

To illustrate the modification of each subsystem due to the coupling, we determine the deviation of the Raman and cavity fluctuations  $\delta Q^2$  and  $\delta x^2$  from the uncoupled case as

$$\delta Q^2 = \frac{\langle \hat{Q}^2 \rangle - \langle \hat{Q}^2 \rangle_0}{\langle \hat{Q}^2 \rangle_0}, \quad \delta x^2 = \frac{\langle \hat{x}^2 \rangle - \langle \hat{x}^2 \rangle_0}{\langle \hat{x}^2 \rangle_0}, \quad (7)$$

where  $\langle \dots \rangle$  denotes the expectation value for a finite coupling  $g$  and  $\langle \dots \rangle_0$  the expectation value in the absence of coupling and cavity nonlinearities ( $g = g_4 = 0$ ). As in the previous section,  $\hat{x}$  is the cavity coordinate which is related to the electric field,  $\hat{E}_{\text{cav}} = \sqrt{2\omega_c} E_0 \hat{x}$ , where  $E_0$  is the electric field amplitude of the noise of the cavity mode. Note that also  $\delta x^2 = [(\langle \hat{E}_{\text{cav}}^2 \rangle - \langle \hat{E}_{\text{cav}}^2 \rangle_0)/\langle \hat{E}_{\text{cav}}^2 \rangle_0]$  is the variation of the quantum fluctuations in the electric field. To compute these Raman and cavity fluctuations we set the probe field  $E_p(t)$  in Eqs. (3)–(5) to zero and average over steady states of the Langevin equations of motion [62].

In Fig. 3 we show  $\delta Q^2$  and  $\delta x^2$  as well as the Raman coordinate  $Q = \langle \hat{Q} \rangle$  for different cavity frequencies and coupling strengths  $g$ . In all cases, a clear resonance can be seen around  $\omega_c \approx \omega_R/2$  indicating a resonant regime in which both the Raman mode and cavity fluctuations are strongly modified. In this regime, the Raman fluctuations are suppressed by the cavity,  $\delta Q^2 < 0$ , so the Raman mode is localized while the cavity fluctuations are amplified by the Raman mode  $\delta x^2 > 0$ . Outside this resonant region the Raman fluctuations are unaffected and remain the same as in free space ( $\delta Q^2 \approx 0$ ). In a similar way, for off-resonant cavity frequencies, quantum vacuum fluctuations remain practically unchanged [71] meaning that the Raman medium barely perturbs the photon field ( $\delta x^2 \approx 0$ ). This

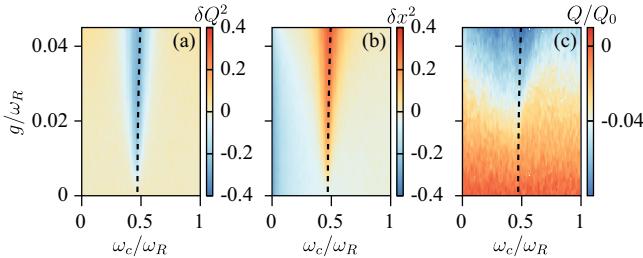

FIG. 3. (a),(b) Variation of Raman and cavity fluctuations compared to the uncoupled case  $g = 0$  (see text) for different cavity frequencies and coupling strengths  $g$ . (c) Raman displacement in units of the quantum oscillator length associated to the Raman mode  $Q_0 = \sqrt{\hbar/M\omega_R}$ . The dashed lines represent the parametric resonant condition  $\omega_R = 2\tilde{\omega}_c$ . On resonance, the main features of parametric Raman polaritons appear: localization (a) and shift (c) of the Raman mode in favor of cavity field amplification (b). The decay rates and nonlinear interaction  $g_4$  are the same as in Fig. 2.

observation justifies our choice to consider the coupling of a single cavity mode with a single Raman mode: due to the resonant character of the interaction, we expect that other off-resonant modes do not contribute.

For the parameters used in Fig. 3, on resonance and close to the instability  $g \approx \sqrt{g_4\omega_R}/2$ , the Raman mode is strongly localized by  $\sim 40\%$  compared to the case of Raman fluctuations in free space while the photon field increases by the same amount with respect to the empty cavity case, even though the coupling is only  $g \sim 4\%\omega_R$ . We emphasize that the values  $g$  used here are of the same order of magnitude as the decay rates  $\gamma$  and  $\kappa$ . Therefore the system is between the weak and strong coupling regime but not in the ultrastrong coupling situation ( $g > \omega_c$ ), where these resonant effects may be more pronounced [72].

In Fig. 3(c) the expectation value of the Raman coordinate  $Q$  is shown as a function of coupling strength  $g$  and cavity frequency  $\omega_c$ . A clear shift of the Raman coordinate is observed for large values of  $g$  which represents another form of control of the Raman mode by the cavity field. This is reminiscent of displacive excitation of coherent phonons [73–75]. However in the scenario considered here, the phonon shift occurs in equilibrium. Thus, the Raman mode is not only localized but also its coordinate is shifted by the vacuum fluctuations. This shift is an off-resonant process and therefore depends only weakly on the parametric resonance compared to the fluctuations in Figs. 3(a) and 3(b).

We have checked that these parametric resonances in  $\delta Q^2$ ,  $\delta x^2$  and shift in  $Q$  also occur for thermal states and survive for stronger nonlinearities  $g_4$  and larger decay rates [62]. Interestingly, thermal fluctuations are less effective in localizing the Raman mode and amplifying cavity fluctuations, but create a larger shift in the Raman coordinate.

*Experimental platforms*—Our mechanism can be realized in materials hosting Raman modes, coupled resonantly with a cavity in the THz range. Interestingly, the strong coupling regime between infrared phonons and a tunable THz cavity has been experimentally demonstrated [36] opening the door to the study of Raman-active materials in cavities using Raman spectroscopy [Fig. 1(a)]. Possible material candidates might be functionalized graphene nanoribbons with Raman activity around 6 THz [76], twisted bilayer graphene with low Raman modes  $\lesssim 3$  THz [77] or transition metal dichalcogenides (TMDs) with ultralow modes below 1 THz. All these examples lie in the experimental frequency range of up to  $\sim 8$  THz in different types of cavities [36,37,78,79].

The Raman-cavity coupling between the cavity mode and the zero-momentum Raman mode can be computed from first principles through the Raman tensor [62] and is given by

$$\frac{g}{\omega_R} = \frac{\sqrt{N}}{2} \frac{\epsilon_0 E_0^2 V_{\text{cell}}}{\omega_R} \tilde{R}, \quad (8)$$

where  $\epsilon_0$  is the vacuum permittivity,  $V_{\text{cell}}$  is the volume of the unit cell of the material hosting the phonon mode and  $N = (V_{\text{samp}}/V_{\text{cell}})$  is the total number of unit cells in the sample of volume  $V_{\text{samp}}$ . The dimensionless Raman coupling is given by  $\tilde{R} \propto \vec{e}_c \cdot \partial_Q \underline{\epsilon}(Q) \cdot \vec{e}_c$ , which measures the change in the electric permittivity  $\underline{\epsilon}$  as a function of a shift of the Raman coordinate  $Q$  per unit cell, and  $\vec{e}_c$  is the polarization vector of the cavity. The electric field noise of a cavity is given by,  $E_0 \sim \sqrt{(\omega_c/\epsilon_0 V_{\text{eff}})}$  [37] and therefore, on parametric resonance  $\omega_R = 2\omega_c$ , we estimate that  $(g/\omega_R) \sim (\sqrt{V_{\text{samp}} V_{\text{cell}}}/V_{\text{eff}})\tilde{R}$ .

To circumvent the possible limitation of weak  $g$  in Fabry-Pérot cavities, due to the small value of  $V_{\text{cell}}/V_{\text{eff}}$ , split-ring resonators (SRRs) cavities could be a solution where large cavity mode volume compression has been experimentally demonstrated. Typically, SRRs are build with cavity frequencies between 0.5–1 THz [78–80] which matches the range of breathing Raman modes of the order of 1 THz in twisted-TMDs like MoSe<sub>2</sub> or WSe<sub>2</sub> [66,81]. Thus the condition  $2\omega_c = \omega_R$  can be satisfied. From the above expression we may expect that also the coupling strength will be particularly increased for these twisted bilayer system of triangular lattices for twist angles around 0° or 60°, where the unit cell becomes very large. Considering 10 × 10 nm for the area of the unit cell, 1 μm<sup>2</sup> for the effective cavity area of SRRs,  $g/\omega_R \sim 0.01$  assuming  $\tilde{R} \sim 1$  as estimated for twisted TMDs using density functional theory [66]. For this  $g$  we estimate that in the quantum noise limit  $2\delta \sim 0.03$  THz,  $Q \sim -0.02Q_0$  (typically below 1 picometer),  $\delta Q^2 \sim -0.2$  and  $\delta x^2 \sim 0.2$ .

*Conclusions*—We have presented how parametric resonances in Raman-cavity hybrids can be exploited to amplify photon quantum noise and localize Raman modes *at equilibrium*. Our Letter represents a proof of principle of how this nonlinear type of hybridization between Raman modes and photons, at the quantum fluctuation level, gives rise to equilibrium parametric amplification that can be leveraged to control quantum materials. In particular, the cavity control of Raman-active phonons demonstrated here is a crucial step towards cavity-material engineering in more complex systems leading to a phase transition as opposed to similar optomechanical few-body realizations. Strongly coupled Raman phonons are responsible for superconductivity in K<sub>3</sub>C<sub>60</sub> [82], and statically shifting one of these modes was proposed as a mechanism for photoinduced superconductivity [13,39]. More broadly, Raman phonons can change lattice symmetries, lift electronic orbital degeneracies [83], gap out gapless electronic systems [84] and manipulate spin-spin interactions [85]. Our Letter paves the way to new studies on all of these topics and the search of similar equilibrium parametric amplification in different scenarios such as Higgs-light hybrids in superconducting systems and in the quantum information realm using the recent three-photon

quantum-optics development [86,87]. We further note that the process described here represents the opposite process to the parametric down conversion from one photon to two phonons [88–90], and analogous conclusions could be extended to these examples. Finally, extending our analysis to multiple modes is a promising route to explore sum-frequency excitations of the Raman mode [91–93] in equilibrium.

- [70] Our calculations correspond to the quantum noise limit at zero temperature where only Stokes peaks show up. In the presence of thermal fluctuations, at finite temperature, both Stokes and anti-Stokes peaks appear in the spectrum that we present in the Supplemental Material [62] for completeness.
- [71] In the limit of small cavity frequencies, the nonlinearities of strength  $g_4$  become relevant, which tends to suppress the cavity fluctuations ( $\delta\chi^2 < 0$ ) weakly with respect to the case of  $g = g_4 = 0$ .
