A new scheme for accelerating electrons, employing a bunched relativistic electron beam in a cold plasma, is analyzed. We show that energy gradients can exceed 1 GeV/m and that the driven electrons can be accelerated from $\gamma_0 mc^2$ to $3\gamma_0 mc^2$ before the driving beam slows down enough to degrade the plasma wave. If the driving electrons are removed before they cause the collapse of the plasma wave, energies up to $4\gamma_0^2 mc^2$ are possible. A noncollinear injection scheme is suggested in order that the driving electrons can be removed.

In the past several years, the laser-plasma interaction as a mechanism for charged-particle acceleration has attracted interest¹ because of the large electric field which a plasma can support ($\sim 100 \text{ GeV/m}$). However, these "beat-wave" accelerators^{2, 3} rely heavily on the state of the art of laser technologies. For example, the scheme requires a fine tuning⁴ between the plasma frequency ω_p and the beat-wave frequency of the laser in order that the wake plasma wave excited by the laser beat wave grows linearly. This in turn either puts a severe constraint on the uniformity of the plasma density, or relies on very high-power lasers to shorten the time of growth. In addition, it may be necessary to deliver the laser energy in a pulse shorter than 10 ps in order to avoid competing instabilities.⁵

This Letter presents another scheme for a plasma accelerator. Lasers are not required and large energy gradients are attained. The idea is to inject a sequence of bunched high-energy electrons into a cold plasma. As in the two-stream instability, the streaming electrons lose energy to the background plasma by exciting a wake plasma wave. If a late-coming electron bunch rides on the wave at a proper phase, it will be boosted to a higher energy as a result of the longitudinal electric field in the wave.

Consider a system in which a chain of relativistic electron bunches with initial $\beta_0 = v_b/c \leq 1$ stream through a cold, uniform plasma along the z axis with a constant separation d. With the assumption that the longitudinal spread l_b of each electron bunch is much smaller than the plasma wavelength, λ_p , the whole bunch of q electrons behaves as a single particle with charge Q = qe.

The linearized equation of motion and equation of continuity for the cold, nonrelativistic background plasma are $\partial_t \mathbf{v}_{p1} = -(e/m)\mathbf{E}_1$ and $\partial_t n_{p1} + n_{p0}\nabla \cdot \mathbf{v}_{p1} = 0$, respectively, where \mathbf{E}_1 is the electric field of plasma and beam: $\mathbf{E}_1 = \mathbf{E}_{p1} + \mathbf{E}_{b1}$, where the plasma velocity is $\mathbf{v}_p = \mathbf{v}_p + \mathbf{v}_{p1}$ ($\mathbf{v}_{p0} = 0$), and the plasma density

is $n_p = n_{p0} + n_{p1}$ ($n_{p0} >> n_{p1}$). For N driving-electron bunches, the charge and current densities are

$$\rho_1(\mathbf{x}) = -en_{p1}(\mathbf{x}) - Q \sum \delta(\mathbf{x} - \mathbf{x}_i), \qquad (1)$$

$$\mathbf{J}_{1}(\mathbf{x}) = -en_{p0}\mathbf{v}_{p1}(\mathbf{x}) - Q\mathbf{v}_{b}\sum\delta(\mathbf{x} - \mathbf{x}_{i}), \qquad (2)$$

respectively, where $\mathbf{x} = \rho \hat{\mathbf{e}}_1 + z \hat{\mathbf{e}}_3$ in cylindrical coordinates, \mathbf{x}_i 's are the instantaneous positions of the N bunches, $\mathbf{x}_i = [v_b t + (N-i)d]\hat{\mathbf{e}}_3$, and the summations are over i = 1, ..., N.

The longitudinal electric field in the wake of these N bunches is $\mathbf{E}_1 = -(1/c)\partial_t \mathbf{A}_1 - \nabla \phi_1$. For an ultrarelativistic electron beam, where $\beta_0 \approx 1$, v_b is approximately constant over several plasma wavelengths, even though substantial energy is transferred to the plasma wave. It is thus convenient to work with the variable $\zeta = z - v_b t \leq 0$ which measures the distance behind the last bunch, and we may put $\partial_t = -v_b \partial_{\zeta}$ and $\partial_z = \partial_{\zeta}$. In the Coulomb gauge, the equation for the scalar potential is $\nabla^2 \phi_1 = -4\pi\rho_1$, and that for the vector potential is $\nabla^2 \phi_1 = -(4\pi/c)\mathbf{J}_1 - \beta_0 \nabla \partial_{\zeta} \phi_1$, where ∇_{\perp}^2 is the transverse Laplacian and $(1 - \beta_0^2)$ is neglected.

To solve for ϕ_1 , we take the ζ derivative twice and combine the result with the equations of motion and continuity, and Eq. (1) to obtain

$$\nabla^2 (\partial_{\boldsymbol{\xi}}^2 + k_p^2) \phi_1 = 4\pi Q \sum \partial_{\boldsymbol{\xi}}^2 \delta(\mathbf{x} - \mathbf{x}_i), \qquad (3)$$

where

$$k_n = \omega_n / v_h = (4\pi n_{n0} e^2 / m v_h^2)^{1/2},$$

and

$$\mathbf{x} - \mathbf{x}_i = \rho \hat{\mathbf{e}}_1 - [(N - i)d - \zeta]\hat{\mathbf{e}}_3$$

The solution of this equation requires that we solve

$$(\partial_{\zeta}^{2} + k_{p}^{2})\phi_{1} = -Q \sum \partial_{\zeta}^{2} (1/|\mathbf{x} - \mathbf{x}_{i}|), \qquad (4)$$

(9)

which has the solution⁶

$$\phi_{1}(\rho, \zeta) = Q \sum \left\{ -(1/|\mathbf{x} - \mathbf{x}_{i}|) + k_{p} \int_{-\infty}^{\zeta} d\zeta' \sin k_{p} (\zeta - \zeta') (1/|\mathbf{x}' - \mathbf{x}_{i}'|) \right\},$$
(5)

where $\zeta' = z' - v_b t$ and $|\mathbf{x}' - \mathbf{x}'_i| = \{\rho^2 + [(N-i)d - \zeta']^2\}^{1/2}$. A favorable aspect of our acceleration scheme is that the phase velocity, ω_p/k_p , of this plasma wave is the same as the beam velocity, v_b . This contrasts with the two-stream instability observed in a continuous beam. In that case, even though the phase velocity is shifted slightly below velocity, the corresponding γ may be significantly below the γ of the beam.⁷ This would be a serious disadvantage for the purpose of collective particle acceleration.

Next, turn to the vector potential A_1 . Taking the ζ derivative on both sides of the equation for the vector potential, and invoking the equation of motion for the current term, we obtain

$$\partial_{\boldsymbol{\zeta}}(\nabla_{\perp}^{2} - \beta_{0}^{2}k_{p}^{2})\mathbf{A}_{1} = -\beta_{0}\nabla(\partial_{\boldsymbol{\zeta}}^{2} + k_{p}^{2})\phi_{1} + 4\pi Q\boldsymbol{\beta}_{0}\boldsymbol{\Sigma}\partial_{\boldsymbol{\zeta}}\delta(\mathbf{x} - \mathbf{x}_{i}).$$
(6)

In combination with Eq. (4), the above equation decouples entirely from the scalar potential. With removal of the ζ derivative common to each term, this equation further reduces to an inhomogeneous modified Helmholtz equation in two dimensions for each component of A_1 .

We are actually interested in the wake field trailing behind the N bunches on the z axis, i.e., at position $\mathbf{x} = z \hat{\mathbf{e}}_3$. In that case

$$\phi_1(\zeta) = -\frac{2\pi Q}{\lambda_p} \sum \left\{ \frac{1}{k_p \left[(N-i)d - \zeta \right]} k_p \int_{-\infty}^{\zeta} d\zeta' \frac{\sin k_p \left(\zeta - \zeta' \right)}{k_p \left[(N-i)d - \zeta' \right]} \right\},\tag{7}$$

where $\lambda_p = 2\pi k_p^{-1}$, and the corresponding vector potential in Eq. (6) reads⁸

$$A_{1z}(\zeta) = -\frac{2\pi Q}{\lambda_p} \sum_{\beta_0^2} \int_0^\infty d\rho' K_1(\beta_0 k_p \rho') \frac{{\rho'}^2}{\{\rho'^2 + [(N-i)d - \zeta]^2\}^{3/2}},$$
(8)

bunch is

where K_1 is the modified Bessel function of order 1. Plots of ϕ_1 and A_{1z} as functions of $|\zeta|$ are shown in Fig. 1, where N = 5 and $d = \lambda_p$. Although A_{1z} diminishes monotonically, ϕ_1 remains oscillatory.

The longitudinal electric field is computed by taking ζ derivatives since $E_{1z} \approx \partial_{\zeta} (A_{1z} - \phi_1)$. The maxima of E_{1z} are at $|\zeta| \simeq (n + \frac{1}{2})\lambda_p$, where *n* is any nonnegative integer, and the contribution to the maximum E_{1z} comes predominantly from the scalar potential. If the separation between the driven bunch and the last driving bunch is such that $|\zeta|$ is around $\lambda_p/2$, the energy

 $\epsilon = -eE_{1z} \simeq 8\pi^2 eQ/\lambda_p^2.$

gradient attainable for each electron in the driven

As an example, consider a plasma of density $n_{p0} = 10^{15}$ cm^{-3} (which sets the limit on the longitudinal bunch spread: $l_b \ll \lambda_p \approx 1.0$ mm). If each bunch consists of $q = 5 \times 10^{10}$ particles, Eq. (9) shows that $\epsilon \approx 2.4$ GeV/m. This treatment ignores nonlinear plasma effects and self-consistency effects that act to slow the driving bunches. It is only valid if the electric field does not approach the cold wave-breaking amplitude, and if the electric energy is small compared to the free energy of the driving bunches. The first condition provides an upper limit on the maximum allowed energy gradient, $\epsilon_{\rm max} \simeq (n_{p0})^{1/2}$ eV/cm $\simeq 3.2$ GeV/ m > 2.4 GeV/m, so our linear theory is still reasonable. The second condition requires that $(E_{1z}^2/8\pi)L$ $< q \gamma_0 mc^2/A$, where L is the length of the beamplasma interaction region and A is the beam area. For the above example, and $100-\mu m$ radii bunches, this limits the effective acceleration length to $L < 0.74\gamma_0$ cm.

To complement the above analytic treatment selfconsistent numerical simulations have been done by use of a one-and-two-halves dimensional (x, v_x, v_y, v_z) , relativistic, fully electromagnetic, particle code. Two bunched electron beams with mean densities of 10^{-3} and 10^{-5} relative to background electron plasma served as the driving and driven beams, respectively. Bunching was represented by density profiles of the form $1 + \sin kx$, 180° out of phase for the two beams. Each beam was initially monoenergetic with momentum $(\beta\gamma)_0 = 5.9$, and had sixteen bunches within the 2048-gridpoint periodic system. The speed of light was chosen to satisfy $k\beta c = \omega_p$ in order to best excite the plasma wave. Since the background plasma had an initial temperature $T/mc^2 = 10^{-3}$, this wave had essentially zero group velocity.

Figure 2 shows the momentum distribution of the two beams at the time $(\omega_p t = 88)$ when the maximum momentum, $(\beta \gamma)_{max} = 16$, was attained. The wave grew so that the bulk of the driving and driven electrons were in the regions of greatest negative and positive force, respectively. The driving electrons lost momentum to the wave until they were significantly slower than the wave, i.e., until $\beta \gamma \approx 1$. They quickly fell behind the wave until they reached the accelerating region, where they regained momentum and energy from the wave until it essentially vanished. Except for the relatively short interval when the driving electrons fell behind the wave, the force on the bulk of the driven electrons was equal in magnitude to that on the driving electrons, but always positive. Thus we expect $(\beta\gamma)_{\rm max} \approx 3(\beta\gamma)_0 - 2$, which was well satisfied in our simulation.

The cycle of wave growth and decline repeated as the simulation continued. However, further acceleration of the driven electrons did not occur. In falling behind the wave by a half wavelength, most of the driving electrons had come into phase with the maximally accelerated driven electrons, and both groups were decelerated together as the wave was recreated during the second cycle.

FIG. 2. Momentum distribution of the driving- and driven-electron beams when the latter has attained its maximum upper limit.

One way to continue the acceleration of the driven electrons is to remove the driving beam from the plasma before it begins to destroy the wave. Therefore, the previous simulation was repeated (but with $T/mc^2 = 10^{-6}$), and when the maximum wave amplitude was attained ($\omega_p t = 48$), the charge of the driving electrons was set equal to zero.

Figure 3 shows the momentum distribution at $\omega_p t = 512$, when the driven electron momenta were as large as $\beta\gamma = 69.5$ and were still increasing. A more recent run gave maximum attainable value of $(\beta\gamma)_{max} = 130$ at $\omega_p t = 1568$. This agrees well with the modified⁹ wave-breaking limit of Tajima and Dawson, $(\beta\gamma)_{max} \approx 4(\beta\gamma^2)_0 = 142$. The behavior of the lowest-energy driven electrons suggest that the velocity of the wave had increased to $\beta\gamma \approx 9$ for the later stages of the simulation, probably because these lower-energy driven electrons were serving as a weak driver for the wave. We speculate that this effect may enable one to achieve still higher energies.

In the first simulation, the maximum energy was gained by those electrons in the region of maximum positive force, one-half wavelength behind the bulk of the driving electrons. In the second, the maximum energy was gained by those electrons initially at the potential-energy peak of the wave, three-quarter wavelengths behind the driving bunches. Use of beams 270° out of phase would double the relative number of high-energy electrons. However, the large number of low-energy driven electrons can be reduced only by use of significantly shorter driven bunches.

Experimentally, it may be possible to remove the driving electrons from the acceleration region by employing a noncollinear injection scheme.¹⁰ The basic idea is to inject two sets of electron bunches at a slight

FIG. 3. Momentum distribution of the driven electrons before the maximum upper limit is attained. This case differs from that of the preceding figure in that driving beam is removed from the system when the plasma wave reaches its maximum amplitude, at which time the driving beam has the momentum distribution shown. Note the different scales in the two figures.

angle, 2θ , towards each other and then accelerate particles down the axis of symmetry in the superposed wake fields of the two intersecting beams. In this way, the electrons in the driving bunches may pass out of the interaction region before they can reabsorb the accelerating waves. Such a scheme also allows one to stage the driving beams by bringing in fresh driver beams at different positions.

An advantage of this noncollinear injection scheme is that the effective phase velocity \tilde{v}_{ph} of the superposed wake field can be controlled by selecting the angle of the two intersecting waves, i.e., $\tilde{v}_{ph} = v_{ph}/$ $\cos\theta > v_{ph}$ (= v_b). In principle, one can choose an angle θ such that \tilde{v}_{ph} is larger than c. However, since the energy gain is limited by the finite spatial extent of the interaction region, which is proportional to $\sin^{-1}\theta$, there should be an optimum angle that gives maximum energy gain per stage. A detailed discussion will be reported elsewhere.
