(Received 25 January 2007; published 29 June 2007)

Type-I edge-localized modes (ELMs) have been mitigated at the JET tokamak using a static external $n = 1$ perturbation field generated by four error field correction coils located far from the plasma. During the application of the $n = 1$ field the ELM frequency increased by a factor of 4 and the amplitude of the D_α signal decreased. The energy loss per ELM normalized to the total stored energy, $\Delta W/W$, dropped to values below 2%. Transport analyses shows no or only a moderate (up to 20%) degradation of energy confinement time during the ELM mitigation phase.

The foreseen baseline operating scenario for International Thermonuclear Experimental Reactor (ITER) [1] is the type-I ELMy H mode [2]. This plasma scenario has been widely studied and the extrapolation of its confinement properties toward ITER should allow operation at a fusion gain (ratio between fusion power and input power) of $Q = 10$ due to the existence of an edge transport barrier. The increase of temperature and density gradients at the plasma edge leads on the one hand to a substantial gain in stored energy and fusion performance, but on the other hand, the pressure gradient reaches a critical limit above which so-called type-I edge-localized modes (ELMs) become unstable [3]. ELMs lead to a periodic expulsion of a considerable fraction of the stored energy content onto the plasma facing components. Although ELMs may be beneficial in controlling the particle inventory and removing fusion products, the associated energy losses are unacceptable. Extrapolation based on present machines indicates that the transient heat loading in ITER will probably be so high that it will lead to melting and a strong reduction in component lifetime [4]. A further problem that already arises in present tokamaks is that the coupling of radio frequency heating power to the plasma becomes poor in the presence of large ELMs.

Recent experiments have shown that by tailoring the plasma shape and the gas injection, H-mode regimes [5] with small ELMs can be accessed on smaller machines. However, on larger machines such as JET, this is only

possible over a limited range of plasma parameters [6]. Active methods of ELM control with the goal to reducing the power loading are therefore required. Several possible control mechanisms are presently under discussion: (i) vertical plasma oscillations to trigger ELMs [7], (ii) pellet pacemaking of ELMs [8], (iii) edge ergodization by resonant magnetic perturbations [9], or (iv) enhanced toroidal field ripple [10]. The application of magnetic perturbations offers a particularly attractive possibility for controlling the edge pressure gradient and therefore ELM stability. Earlier experiments have shown that magnetic perturbations ($n > 4$) can trigger small ELMs in otherwise ELM-free plasmas on JFT-2M [11] and perturbation fields with $n = 1$ and $m = 4-5$ were able to increase the frequency of type-III ELMs on COMPASS-D [12]. DIII-D has an internal coil system which allows the generation of magnetic field perturbations with a toroidal mode number of $n = 3$ which has completely suppressed type-I ELMs in collisional and collisionless plasmas [9,13]. In all of the above experiments the coil systems used to impose the magnetic field perturbation were built into the vacuum vessel. In view of designing the next generation tokamaks, ELM control through the application of low- n perturbation fields generated by external coil systems is an attractive solution that needs further exploration.

On JET, external perturbation fields can be applied by the error field correction coils (EFCCs) [14]. The system

consists of four square shaped coils (~ 6 m in dimension) located in octants 1, 3, 5, and 7 (fourfold toroidally symmetry) which are mounted vertically between the transformer limbs. Each coil spans a toroidal angle of 70° and has a radial distance along the winding of 5.3 to 7 m from the axis of the machine. It has 16 turns and the maximum total coil current amounts to $I_{\text{EFCC}} = 48$ kAt. The coil system can be wired in $n = 1$ and $n = 2$ configurations. In this Letter, the first results from active ELM control experiments on JET using the EFCCs in $n = 1$ configuration are presented.

An overview on an ELM mitigation pulse is shown in Fig. 1. The traces are (a) the total input power, P_{tot} , and the stored energy, W_{dia} , (b) I_{EFCC} , (c) the line-integrated electron densities, $n_e l$, measured with an interferometer along two lines of sight, one close to the magnetic axis (upper trace) and the other near the pedestal top (lower trace), (d) the electron temperature, T_e , from the ECE diagnostic measured near the center (upper trace) and at the pedestal top (lower trace), (e) the D_α signal measured at the outer divertor, (f) the fast ion loss current, I_{loss} , measured by Faraday cups [15], and (g) a signal measured by a magnetic pickup coil. The pulse had a toroidal magnetic field of $B_t = 1.84$ T and a plasma current of $I_p = 1.6$ MA, corresponding to an edge safety factor of $q_{95} = 4.0$. The target plasma in these experiments had a low triangularity shape ($\delta = 0.3$). The electron collisionality at the pedestal is ~ 0.09 . The $n = 1$ perturbation field created by the EFCCs has a half-sine shaped waveform for 1.2 s, which is by a factor of ~ 5 longer than the plasma energy confinement time. As soon as the I_{EFCC} reached a critical value

of ~ 10 kAt at the edge density [lower trace in (c)] started to drop. This so-called pump-out effect is a typical signature for ergodization of the edge plasma [16]. When the EFCC current increased further, the D_α signal (e) measuring the ELMs showed a strong reduction in amplitude. The ELM frequency increased from 30 Hz to 120 Hz. The periodic change in T_e at the edge pedestal [lower trace in (d)] due to the ELM crashes was reduced from 500–700 eV to 100–200 eV. Whereas the central $n_e l$ decreased during the EFCC phase, T_e measured near the plasma center increased. The energy loss per ELM normalized to the total stored energy, $\Delta W/W$, measured by the fast diamagnetic loop decreases from $\sim 7\%$ to values less than $\sim 2\%$ (estimated as an upper bound by assuming the convected power between ELMs to be zero). A strong reduction in the amplitude of magnetic perturbations due to the ELM bursts was observed when the type-I ELMs were mitigated by the $n = 1$ field to be more frequent and smaller in amplitude [Fig. 1(g)]. The losses of fast particles at the low-field side (LFS) were decreased during the EFCC phase as shown in Fig. 1(f).

The changes of the plasma profiles are shown in Fig. 2. The electron temperature T_e (a) in the plasma core increases during the ELM mitigated phase by 20%, while T_e at the pedestal stays almost constant (note that the profile shifts inward, see discussion below). Ion temperature T_i (b) increases in the core by 23%. The electron density (c) decreases everywhere and the toroidal rotation profile (d) exhibits strong braking by the $n = 1$ perturbation field, as it has been recently observed on JET [17]. For the ELM mitigation the amplitude of the external pertur-

bation field has been kept below the threshold for excitation of a locked mode.

Figure 3 compares the changes of the T_e profile before and after an ELM with and without application of the $n = 1$ perturbation field. The amplitude of the drop in electron temperature caused by an ELM, ΔT_e , is reduced by about a factor of 4 when the type-I ELMs are mitigated with the $n = 1$ field.

The effect of the nonaxisymmetric perturbation field on the ELM behavior has been systematically investigated with respect to the diagnostic layout and the location of the plasma control sensors. The EFCCs can be operated in different phases (orientations of the resulting radial field vector with respect to the vacuum vessel), depending on the current direction and amplitude in each coil pair. By using the same current in each pair of coils four different phases can be selected by reversing the current direction in one or both coil pairs. The pump-out effect, the reduction in ELM amplitude, the simultaneous increase in ELM frequency, and the reduction in fast ion losses were observed for all four phases.

However, a difference was found when the temperatures of the outboard limiters (located at octant 3), T_{lim} , were compared. Figure 4(b) shows an example for the time evolution of T_{lim} during the H-mode phase. T_{lim} starts to rise after the neutral beam heating ($P_{NBI} = 16.8$ MW) was applied. The application of the $n = 1$ field led to a reduction in T_{lim} in only two of the investigated phases; the other phases showed even a faster increase. This finding can be explained by the interaction of the position and shape controller with the $n = 1$ perturbation. The controller acts on the plasma by applying axisymmetric fields. The position and shape measurement is done by a set of magnetic sensors located at dominantly the same toroidal location. The $n = 1$ perturbation field leads to (i) a kinklike displacement of the plasma column and (ii) tilts the plasma since the perturbation field strengthens the radial field on one side of the torus and weakens it on the opposite side. The position and shape feedback reacts in a way that the position of the plasma column at the location of the sensors is restored by moving the plasma vertically and either shrinking or expanding the plasma column. This may result

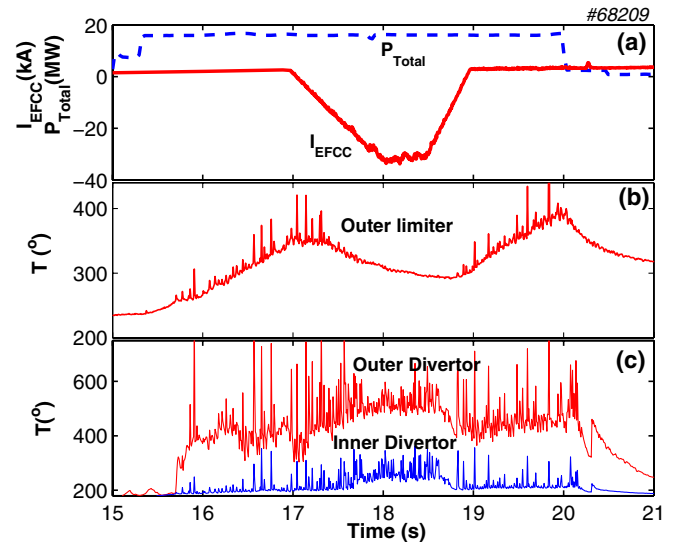

FIG. 4 (color online). Time evolution of (a) I_{EFCC} , total input power (P_{total}), temperatures of (b) an outboard limiter, (c) outer and inner divertor tiles (measured by an ir camera) during the ELM mitigation phase.

in an outward shift on the opposite side which decreases the gap between the limiter and the separatrix. The drop in T_{lim} is observed when the resulting action of the shape controller leads to a slight shrinking of the plasma. Here, the two phases, which resulted in a drop of T_{lim} during the application of the $n = 1$ field, were identified. The increase of the temperature on the outer and inner divertor tiles (T_{out} and T_{in}) are observed when the $n = 1$ field is applied with correct phasing as shown in Fig. 4(c). The results from a power balance analysis show that the total energy deposited in the divertor increased by a few percent for the pulses with correct phasing and decreased when the wrong phases were chosen (NB: the $n = 1$ fields was only applied during 25% of the main heating phase). It is important to note that the ELM mitigation was found for *all* phases of the perturbation field investigated, independent on an increase (with wrong phasing) or decrease (with correct phasing) of the recycling flux at the outer limiter, thus ruling out an increased recycling as the cause of the enhanced ELM frequency [18].

In a second series of experiments the dependence of the ELM mitigation effect on the edge safety factor, q_{95} , was investigated. Results from DIII-D have shown that with $n = 3$ perturbation fields, the edge safety factor was a crucial quantity and ELM suppression was only achieved within a narrow range [9]. In the JET experiments, q_{95} was varied between 3.0 and 4.8. ELM mitigation was achieved for all values of q_{95} . The minimum perturbation field amplitude above which the ELMs were mitigated, I_{ELM}^{min} , increased but always remained below the $n = 1$ locked mode threshold, I_{LM} . And the values of I_{ELM}^{min}/I_{LM} for q_{95} of 4.8, 4.0, 3.5, and 3.0 are 12.8/(>36.8), 16/36.8, 19.2/32.0, and 22.4/30.4 kAt/kAt.

FIG. 5 (color online). The thermal energy confinement time from TRANSP modeling normalized to the IPB98(y,2) value shows almost no decrease.

Transport analysis using the TRANSP code [19] shows that the thermal energy confinement time, τ_{therm} , drops because of the density pump out, but when normalized to the IPB98(y,2) scaling (which describes the thermal energy confinement in the ELMy H mode for a nominal ITER fusion factor $Q = 10$ discharge) [1] it shows almost no reduction (Fig. 5). The loss of energy content due to the reduction in density and temperature at the edge is almost compensated by an increase of the central temperatures.

The increase in f_{ELM} has been observed when the $n = 1$ field is applied. This observation is different to the results from DIII-D, where the type-I ELMs are completely suppressed with an $n = 3$ resonant magnetic perturbation. The density pump-out effect and the changes in the edge temperature profile are similar [9].

The dependence of both f_{ELM} and the amplitude of ΔT_e on I_{EFCC} was as shown in Figs. 6(a) and 6(b). When the current in the EFCCs increased above the critical value of ~ 16 kAt (what corresponds to a radial perturbation of 1.6 mT on the plasma surface), the ELM frequency started to increase while the drop in T_e during the ELM collapse decreased. A further increase of I_{EFCC} actively controlled both f_{ELM} and ΔT_e . However, this dependence is found to be different between ramp-up and ramp-down of I_{EFCC} which could be due to a hysteresis effect or nonstationary nature of the experiment. Figure 6(c) shows the clear dependence of the amplitude of ΔT_e on the drop of edge line-integrated density (pump-out effect), $\Delta n_e l$, without hysteresis.

Figure 7 shows a Poincaré plot of the magnetic field lines for $I_{\text{EFCC}} = 36.8$ kAt. The calculation is based upon an equilibrium reconstructed for the pulse shown in Fig. 1 with the perturbing field in vacuum superimposed.

FIG. 6 (color online). (a) Frequency of the ELMs, f_{ELM} , and (b) the amplitude of ΔT_e as a function of I_{EFCC} . (c) Dependence of ΔT_e on the density drop due to the pump-out effect.

Screening effects due to plasma rotation have been neglected. The magnetic surfaces at the plasma edge ($\rho > 0.95$) were ergodized by the $n = 1$ perturbation for an amplitude of the resonant components, $B'_{m,1}$, of a few Gauss at the corresponding rational surfaces. The Chirikov parameter at the plasma edge was ~ 1.4 for $I_{\text{EFCC}} = 36.8$ kAt and ~ 1 for $I_{\text{EFCC}} = 16$ kAt which is the critical threshold found for ELM mitigation in this plasma.

ELM mitigation with an $n = 1$ field was also found to work in high beta plasmas ($\beta_N = 3$; $B_t = 1.8$ T and $I_p = 1.2$ MA) without degradation of energy confinement time. These results confirm that the ELM mitigation using an

FIG. 7. Poincaré plot for the plasma parameters of Fig. 1 and an EFCC current of 36.8 kAt. The Chirikov parameters for $I_{\text{EFCC}} = 36.8$ kAt (\times) and 16 kAt (\circ) are plotted.

external $n = 1$ perturbation has a wide operational window for different target plasmas.

In conclusion, the experimental results from JET show that both the frequency and the amplitude of type-I ELMs can be actively controlled with an acceptable reduction in the plasma confinement by the application of an $n = 1$ perturbation field generated by external coils. The normalized energy loss per ELM, $\Delta W/W$, dropped to values below 2%. ELM mitigation does not depend on the phase of the applied $n = 1$ external field. There is a wide range in q_{95} (4.8–3.0) in which ELM mitigation with the $n = 1$ field has been observed. These results are of importance not only for understanding the physics of ELMs, but also for the active control of type-I ELMs in future machines, such as ITER.

This work was done under the JET-EFDA work-programme [20].
