(Received 17 May 2007; published 19 December 2007)

We solve the quantum Hall problem exactly in a limit and show that the ground states can be organized in a fractal pattern consistent with the Haldane-Halperin hierarchy, and with the global phase diagram. We present wave functions for a large family of states, including those of Laughlin and Jain and also for states recently observed by Pan *et al.*, and show that they coincide with the exact ones in the solvable limit. We submit that they establish an adiabatic continuation of our exact results to the experimentally accessible regime, thus providing a unified approach to the hierarchy states.

A key concept in quantum Hall (QH) physics is that of an incompressible electron liquid. In the integer effect, the formation of this liquid can be understood in terms of independent electrons moving in a magnetic field in the presence of a small but crucial amount of disorder [1]. In the experimentally very similar fractional effect, the electron liquid is formed through the electron-electron interaction. The fractional liquids, the simplest of which are well understood in terms of Laughlin's wave functions [2], are highly correlated quantum systems with remarkable properties.

There are two alternative microscopic approaches to the fractional liquids [3]—the hierarchy and composite fermions. In the former, successive condensation of the fractionally charged quasiparticles leads to a hierarchy of ever more complex QH states [4,5]. In the latter, the electrons bind magnetic flux quanta to form new particles, composite fermions, that see a reduced magnetic field, and the fractional effect is an integer effect of these new particles [6,7]. However, neither composite fermions nor the hierarchy has a solid theoretical foundation, and they may well be complementary views of the same phenomena rather than mutually excluding descriptions [8,9]. The hierarchy construction is closely related to the global phase diagram, see Fig. 1, which provides an overall picture of the QH states. This phase diagram, which can be derived using a Chern-Simons-Ginzburg-Landau approach [10], and exhibits an intriguing modular symmetry [11], is supported by experiments, but deviations have also been reported [12], and its precise status remains an important open problem.

A great advantage of the composite fermion scheme is that it provides very good and explicit wave functions for the Jain states with $\nu = n/(2kn \pm 1)$, n, $k = 1, 2, \ldots$, which can be interpreted as integer QH states of composite fermions. Until recently, all observed states were of this type; in 2003, however, experiments on ultra clean samples revealed states at other fractions, such as 4/11 and 6/17 [13]. These new states point towards a fractal, self-similar structure of states in the lowest Landau level [14]. At present, there are no agreed upon wave functions for these

states and the proper interpretation of them is under debate. In this Letter, we give theoretical support for the global phase diagram and present an explicit realization of the hierarchy in a well-defined and solvable limit. We also report explicit and testable wave functions for the states that are obtained by successive condensation of quasielectrons—these wave functions agree with our exact solution in the solvable limit, and naturally encompass both the Laughlin and Jain wave functions and states such as 4/11, reported in Ref. [13]. For other attempts to construct hierarchy wave functions, some of them with explicit reference to composite fermions, see, e.g., Refs. [9,15].

There is a simple and striking consequence of the experiment in Ref. [13]: QH states are observed at all filling factors $\nu = p/q$ for $q \lesssim q_0 \approx 17$ in the experimental range of ν (here q is odd and p, q are relatively prime), see Fig. 2. A QH experiment is performed on a sample with a certain amount of disorder—the lower the disorder is, the

FIG. 1 (color online). Global phase diagram. The global phase diagram in the filling factor-disorder plane for $1/4 \leq \nu \leq 1/2$ (other regions are similar). Crosses mark fractions where wave functions are constructed using conformal field theory.
FIG. 2 (color online). Observed states and fractal structure. For each rational filling factor, $\nu = p/q \leq 1$, q odd, there is a unique hierarchy state and its stability increases monotonically with $1/q$. The fractal structure of states is manifest. States in the region $2/7 \leq \nu \leq 2/3$ reported in Ref. [13] are marked by crosses; pluses mark fractions were we infer a possible weak signal from the data in Ref. [13]. The horizontal line marks the extent in ν of the experiment and is a line of constant gap and the approximate boundary for the observed states. The inset shows the structure of hierarchy states: At each $\nu = p/q$, q odd, there is a state with gap $\sim 1/q$ and quasiparticles with charge $\pm e/q$. When these condense two sequences of states approaching p/q with decreasing gap are obtained.

more fractions are observed. This defines a notion of stability for a state: a more stable state is seen at higher disorder than a less stable state. Our interpretation of Ref. [13] is that (1) there is a QH state at any $\nu = p/q \leq 1$, q odd, and (2) the stability of the state decreases monotonically with increasing q in agreement with the hierarchy prediction [5].

The statement that there is a QH state for each $\nu = p/q \leq 1$ needs to be qualified. We introduce a parameter L such that the experimental regime is obtained as $L \rightarrow \infty$. When $L \rightarrow 0$ the problem is exactly solvable and the ground state and its quasiparticle excitations have all the qualitative properties of a QH state. If there is no phase transition as L increases, then the QH state is observed at this filling factor. However, phase transitions may occur leading to other states such as Wigner crystals where the repulsion freezes the electrons in a regular lattice, striped states where the electron density varies periodically or a Fermi gas (for even denominators q).

To give a detailed argument for the propositions in the introduction, we proceed in three steps. First we solve the interacting spin-polarized many-electron system exactly for each filling factor $\nu = p/q \leq 1$ in a certain mathematically well-defined limit. We obtain the ground state as well as the fractionally charged quasiparticle excitations. Furthermore, in this limit the hierarchy construction of the

QH states is manifest, and the stability of the states decreases monotonically with q. Second, for each fraction where the state is obtained by (successive) condensation of quasi *electrons* (as opposed to quasi *holes*), see Fig. 1, we present explicit wave functions for the ground state and wave functions for the quasiparticle excitations can also be obtained. These wave functions—which are in the lowest Landau level—are obtained by a unique and natural construction that exploits the intriguing relation between the QH effect and conformal field theory (CFT). They are in 1:1 correspondence with the exact solutions, and reduce to these in the solvable limit. Furthermore, the fractional charge and fractional statistics of the quasiparticles are reflected in the algebraic properties of the CFT operators by which they are created. Third, we argue that this construction establishes the adiabatic continuation of the results in the solvable limit to the experimentally accessible regime (at fractions where a QH state is observed).

The solvable limit is obtained by considering the two-dimensional electron gas on a cylinder with circumference L, and choosing the one-electron states centered along rings around the cylinder—these states are Gaussians with width of order one magnetic length $\ell = \sqrt{\hbar c/eB}$ along the cylinder. This maps the QH problem onto a one-dimensional lattice problem with lattice constant $2\pi\ell^2/L$. A basis of many-electron states is given by $|n_1 n_2, \ldots\rangle$, where $n_k = 0, 1$ depending on whether site k is empty or occupied. When $L/\ell \rightarrow 0$ the overlap between different one-electron states vanishes and the energy eigenstates are simply the states where the electrons occupy fixed positions, $|n_1 n_2, \ldots\rangle$, and the ground state is the one that minimizes the electrostatic repulsion [16]. At $\nu = 1/3$, this is obviously the state where every third site is occupied [17]. For general filling factor, $\nu = p/q$, the ground state is a gapped crystal—or Tao-Thouless (TT) state—with p electrons in a unit cell of length q. For example, at $\nu = 1/3, 2/5, 3/7, \ldots$ the unit cells are 100, $10010 \equiv 10_2 10$, $1001010 \equiv 10_2(10)_2 \ldots$.

The lowest energy charged excitations at $\nu = p/q$ are quasielectrons and quasiholes with charge $\mp e/q$, where $-e$ is the electron charge; in the thin limit these are domain walls in the TT-state and the charge is determined by the Su-Schrieffer counting argument [16,18]. For example, the excitations at $\nu = 1/3$ are obtained by inserting or removing 10. When the filling factor is gradually increased away from $1/3$ a gas of such quasielectrons of increasing density is formed. These repel each other and condense to form new ground states. Eventually, one excitation per unit cell has been added and the new ground state has unit cell 10010—the filling factor is then $2/5$. However, before this happens lower density condensates, with one quasielectron per $2k-1$ unit cells 100 will form, giving new ground states with unit cells $(100)_{2k-1}10$ at filling factors $\nu = 2k/(6k-1)$, $k = 1, 2, \ldots$. Similarly, decreasing the filling factor away from $1/3$ gives the ground states with

unit cells $(100)_{2k-1}1000$ at $\nu = 2k/(6k + 1)$. This pattern is general: The TT-state at $\nu = p/q$ is the parent state for two sequences of daughter states that approach $\nu = p/q$ from above and below and are obtained by condensation of decreasing densities of quasielectrons and quasiholes, respectively, see the inset in Fig. 2. For details and proofs we refer to Refs. [16,19].

To summarize, at each $\nu = p/q \leq 1$, q odd, there is a TT-state, which we argue below develops into a QH state as $L \to \infty$, and these states are formed from other TT-states by condensation of quasiparticles. This may also be interpreted as the quasiparticles filling an effective Landau level as one goes, e.g., from $\nu = 1/3$ to $\nu = 2/5$.

The QH effect is destroyed by disorder—at a certain amount of disorder only states with a stability above some threshold occur. A measure of the stability is the energy it costs to create a quasielectron-quasihole pair. In the thin limit, this decreases monotonically when q increases [19]—in good agreement with the hierarchy prediction [5]. Figure 2 shows $1/q$ for all hierarchy states in the lowest Landau level. There is a unique state at each rational filling factor, so this is simply a plot of $1/q$ for all rational numbers $\nu = p/q$ in the interval [0,1] (where q is odd and p, q are relatively prime). This is a self-similar, fractal, structure—enlarging any interval of ν gives an identical figure. Since the solvable limit predicts that the gap increases with $1/q$, states above some roughly horizontal line should be observed in a given sample. In the figure, the states observed in the interval $2/7 \leq \nu \leq 2/3$ for an extreme high mobility sample [13] are indicated. The agreement with the prediction is surprisingly good. The deviations seen in Fig. 2 may be due to corrections to exact particle-hole symmetry and to the difficulty to observe a weak state that is close to a much more stable state—this for instance explains why the Jain state at $\nu = 10/21$ is observed, but not (yet) the state at $\nu = 7/19$. The latter, which we predict to be on the verge of observation, is interesting in that it would be the first daughter of a non-Jain state. We conclude that Fig. 2 in general determines what states should be observed at given disorder.

We now discuss the phase diagram in the filling factor-disorder plane in the thin limit, making two assumptions: (1) The states with a gap above a certain cutoff are formed at given disorder and this cutoff decreases monotonically with decreasing amount of disorder, and (2) phase transitions between QH states are caused exclusively by condensation of the quasiparticles discussed above. (1) means that Fig. 2 can be thought of as a diagram in the filling factor-disorder plane and (2) implies that the phase boundary for $\nu = p/q$ must contain precisely those states that can be obtained by (successive) condensation of such quasiparticles. For example, the 1/3-dome must extend over $\nu = p/(2p + 1) \to 1/2$ and over $\nu = p/(4p - 1) \to 1/4$ but include no larger or smaller ν. This gives the phase diagram in Fig. 1, where only the topology of the phases

and their relative heights are significant. The topology is identical to the one in the lowest Landau level part of the global phase diagram of Refs. [10,11].

Given the assumptions, this establishes the global phase diagram as $L \to 0$. As $L \to \infty$, the TT-state at any $\nu = p/q$, q odd, develops into a QH state, as will be argued below. If there is no phase transition when L grows, then this state is the ground state in the experimental regime and the QH effect is observed at this filling fraction. However, phase transitions may occur and other states may be observed. We believe that this explains the observed deviations from the global phase diagram, such as the insulating phases near Laughlin fractions [12]. In fact, the even denominator fractions are an example of this phase transition scenario. Even though we have excluded them from the discussion above, the gapped TT-states are the ground states also for these fractions as $L \to 0$. We believe that the well-understood $\nu = 1/2$ case is representative: As L increases, the gapped TT-state, which has unit cell 10, gives way to a state with gapless neutral excitations for $L \sim 5\ell$—a Luttinger liquid; this state then develops smoothly into the observed gapless two-dimensional bulk state [16,20]. This shows that the small L limit may describe also nonhierarchy states.

It is crucial that our results can be extended from the thin cylinder, were they are established, to the experimentally relevant two-dimensional bulk case. First we note that the qualitative features of the TT-states and the QH hierarchy states are the same: they have a gap, the same quantum numbers and, in particular, they have quasiparticles with the same fractional charge. Also note, that while any QH state on a torus shows a periodic variation in the density [21], the approach to homogeneity is very rapid but does not correspond to a phase transition. The two schemes-the thin limit and the CFT approach-give an identical hierarchy of states, this clearly suggests an adiabatic connection.

For a short-range interaction the Laughlin states are the ground states for all L [22]; this establishes that the TT states at these fractions develop continuously into the bulk QH states as $L \to \infty$ without a phase transition. Noting that the problem on a cylinder with circumference L can equivalently be thought of as the infinite two-dimensional case with an L-dependent Hamiltonian, we conclude that the TT state and the bulk QH state are adiabatically connected for the Laughlin fractions (and a short-range interaction). We believe this holds generically for fractions where a QH hierarchy state is observed, i.e., this state is adiabatically connected to the corresponding TT state. This claim is supported by numerical simulations on small systems, where the gap to the first excited state has been shown to remain finite for all odd (but for no even) $q \leq 11$ [16]. Moreover, Jain's wave functions for $\nu = n/(2kn \pm 1)$ reduce to the appropriate TT states as $L \to 0$ [16], thus giving a strong argument for the adiabatic continuity also for these fractions. However, the status of the fractions that

cannot be interpreted as an integer effect of composite fermions has until now been less clear.

Around 1990 it was noted that Laughlin's wave functions take the form of correlation functions in certain conformal field theories [23,24], and it was also conjectured that this is true for general QH states [23,25]. Recently it was shown that the composite fermion wave functions in the Jain sequence $\nu = n/(2kn + 1)$, k, $n = 1, 2, \ldots$ can be constructed from correlators in a CFT with n bosonic fields [26]. A natural extension of this construction gives, for n bosonic fields, a set of wave functions labeled by n positive integers k_i, $i = 1, 2, \ldots n$. If $k_i = 1$ for $i = 2, \ldots n$, then $\nu_n = n/(2k_1 n + 1)$ and the wave functions are Jain's composite fermion wave functions. For a general set $\{k_i\}$, the wave function approaches the TT-ground state in the thin cylinder limit. These fractions, in the interval $[\frac{1}{4}, \frac{1}{2}]$ are indicated in Fig. 1. The k_i's determine the densities of the n condensates of quasielectrons that build up the state—the composite fermion state is the one where all but the first of these condensates have maximal density. Using the methods of Ref. [26] one can construct wave functions also for the pertinent quasihole and quasielectron excitations, and show that the expected charge and statistics properties of these particles are reflected in the algebraic properties [$U(1)$ charge and commutation relations] of the corresponding anyonic operators. Details will be published later, and here we only present the $n = 2$ wave functions for $N = 2k_2 M_2$ particles at positions $z_i = x_i + iy_i$:

$$
\Psi = \sum_{i_1 < i_2 \ldots < i_{M_2}} (-1)^{\sum_m i_m} \partial_{i_1} \cdots \partial_{i_{M_2}}
$$
$$
\times \left[\prod_{i_l, \bar{i}_m} (z_{i_l} - z_{\bar{i}_m})^{2k_1} \prod_{i_l < i_m} (z_{i_l} - z_{i_m})^{2(k_1+k_2)-1} \right.
$$
$$
\left. \times \prod_{\bar{i}_l < \bar{i}_m} (z_{\bar{i}_l} - z_{\bar{i}_m})^{2k_1+1} \right] e^{-\sum_i (|z_i|^2/4\ell^2)},
$$

where $\{i_m\}$ is a subset of M_2 indices, and $\{\bar{i}_m\}$ are the remaining $M_1 = (2k_2 - 1)M_2$ indices. For $k_2 = 1$, Ψ are Jain's wave functions at $\nu = 2/(4k_1 + 1)$, while $k_1 = 1$, $k_2 = 2$ gives our proposal for the observed state at $\nu = 4/11$. The thin limits [16] of the $n = 2$ states are the TT states $(10_{2k_1})_{2k_2-1}10_{2k_1-1}$.

We compared our candidate wave function at $\nu = 4/11$ with exact diagonalization results in the disc geometry. For eight particles, the overlap with the exact ground state is 0.72 and the energy $E_{4/11} = 5.317$ is in good agreement with the exact one, $E_{\text{exact}} = 5.297$ (in units of $e^2/\epsilon\ell$). Preliminary results for a torus, where there are no edge effects, are encouraging.

In summary, we presented theoretical support for the global phase diagram and obtained an explicit realization of the hierarchy of fractional QH states in a solvable limit. For a large class of states, including those of Laughlin and Jain, we presented explicit many body wave functions that represent an adiabatic continuation from the solvable limit to the experimentally relevant region.
