(Received 1 November 2018; published 29 January 2019)

The angular dependence of spin-orbit torque in a disordered Co/Pt bilayer is calculated using a first-principles nonequilibrium Green's function formalism with an explicit supercell averaging over Anderson disorder. In addition to the usual dampinglike and fieldlike terms, the odd torque contains a sizable planar Hall-like term $(\mathbf{m} \cdot \mathbf{E})\mathbf{m} \times (\mathbf{z} \times \mathbf{m})$ whose contribution to current-induced damping is consistent with experimental observations. The dampinglike and planar Hall-like torquances depend weakly on disorder strength, while the fieldlike torquance declines with increasing disorder. The torques that contribute to damping are almost entirely due to spin-orbit coupling on the Pt atoms, but the fieldlike torque does not require it.

Spin-orbit torque (SOT) [\[1\]](#page-4-0), which is a manifestation of relativistic physics in solid-state systems, has attracted considerable interest due to its device applications [\[2\]](#page-4-0) in memory technologies [\[3–7\]](#page-4-0) and spin-torque nano-oscillators [\[8–12\]](#page-4-0). SOT can arise in systems lacking bulk inversion symmetry, such as $(Ga, Mn)As$ crystalline systems [\[13\]](#page-4-0), or in systems lacking structural inversion symmetry. It can be described in terms of the nonequilibrium spin density [\[14–16\]](#page-4-0) and can affect the magnetization dynamics [\[17\]](#page-4-0). For systems containing a heavy-metal/ferromagnet interface, two mechanisms of SOT have been suggested: the inverse spin-galvanic effect (ISGE) [\[18–20\]](#page-4-0) arising at a heavy-metal/ferromagnet interface [\[21–](#page-4-0) [25\]](#page-4-0) and the bulk spin-Hall effect [\[26\]](#page-5-0) originating in the bulk of the heavy metal [\[27–29\]](#page-5-0). These mechanisms lead to the fieldlike $(\mathbf{z} \times \mathbf{E}) \times \mathbf{m}$ and dampinglike $\mathbf{m} \times [(\mathbf{z} \times \mathbf{E}) \times \mathbf{m}]$ terms in SOT, which are, respectively, odd and even with respect to the magnetization described by the unit vector **m**. Other terms with more complicated angular dependence are allowed by symmetry and have been experimentally identified in several systems [\[30–32\]](#page-5-0). Such contributions can arise due to interfacial scattering [\[33\]](#page-5-0), even without any bulk spin Hall effect [\[34,35\]](#page-5-0), and they are sensitive to the treatment of disorder [\[33,36–38\]](#page-5-0). Axially asymmetric contributions to SOT induced by low crystalline symmetry have also been observed [\[39\]](#page-5-0).

The layers in SOT bilayers are usually made about a nanometer thick or even less. The phenomenological notion of an interface between bulk regions, as well as the interpretation in terms of the bulk spin-Hall effect, is, therefore, unjustified, and a fully quantum-mechanical treatment of the whole device is essential. An extreme case is that of a magnetic layer in contact with a topological insulator [\[40,41\]](#page-5-0), which can generate strong SOT [\[42\]](#page-5-0). There is ample experimental evidence of the existence of an interfacial contribution to SOT [\[43–45\]](#page-5-0). *Ab initio* studies of Pt/Py bilayers also suggest the importance of interfacial contributions to the spin-Hall effect [\[46\]](#page-5-0), which should lead to an interfacial SOT.

Most of the existing *ab initio* studies of SOT rely on the use of phenomenological broadening for the Green's functions [\[16](#page-4-0)[,47\]](#page-5-0), which does not capture the full physics of SOT. A calculation of SOT using the coherent potential approximation for disorder averaging was also reported [\[48\]](#page-5-0), but only one orientation of the magnetization was considered.

In this Rapid Communication, we develop the nonequilibrium Green's function (NEGF) approach [\[49\]](#page-5-0) within the tight-binding linear muffin-tin orbital (LMTO) method [\[50\]](#page-5-0) for *ab initio* calculations of SOT in magnetic multilayered systems with explicit treatment of disorder and apply it to study SOT in a Co/Pt bilayer. Our results reveal a complicated angular dependence of SOT, including a sizable planar Halllike contribution.

In our LMTO-NEGF treatment, spin-orbit coupling is included as a perturbation to the second-order LMTO potential parameters $[51,52]$. The spin torque on atom *i* is calculated as $\mathbf{T}_i = \int \mathbf{B}_{xc,in}(\mathbf{r}) \times \mathbf{m}_{out}(\mathbf{r}) d^3 r_i$, where the integral is over the atomic sphere for atom *i*, $\mathbf{B}_{xc,in}(\mathbf{r})$ is the "input" exchangecorrelation field, which is aligned with the prescribed direction of the magnetization, and $\mathbf{m}_{out}(\mathbf{r})$ the "output" magnetization obtained from the NEGF calculation [\[16,](#page-4-0)[53–55\]](#page-5-0). This approach is justified by introducing the constraining fields [\[63\]](#page-5-0) stabilizing the instantaneous orientation of magnetization, whereby the internal spin torque is balanced by the torque of the constraining field [\[55\]](#page-5-0). The spin-density matrix

$$
\hat{\rho}(\mathbf{r}) = -\frac{i}{2\pi} \int_{-\infty}^{\infty} \hat{G}_{<}(E, \mathbf{r}, \mathbf{r}) dE \tag{1}
$$

is obtained [\[49\]](#page-5-0) from the Green's function *G<* of the Keldysh formalism, given by

$$
G_{<} = i G (f_L \Gamma_L + f_R \Gamma_R) G^{\dagger}, \tag{2}
$$

where G and G^{\dagger} are the retarded and advanced Green's functions, $\Gamma_{L/R}$ is the anti-Hermitian part of the self-energy for lead *L* (left) or *R* (right), and $f_{L/R}(E)$ are the occupation functions for the two leads.

The bias *V* is applied symmetrically, shifting both the potential and the chemical potential of the left (right) lead by $\pm eV/2$. In the steady state of a homogeneous metallic conductor with an applied bias, there is a linear potential drop between the leads, while the density is translationally invariant. Thus, instead of performing a self-consistent calculation for the whole system, we impose a linear potential drop and use equilibrium charge and spin densities for all atoms as inputs in the Kohn-Sham Hamiltonian.

Using the identity $G(\Gamma_L + \Gamma_R)G^{\dagger} = i(G - G^{\dagger})$, the integral in Eq. [\(1\)](#page-0-0) is formally split into two parts referred to as the Fermi-sea and the Fermi-surface contributions:

$$
\hat{\rho}_{\text{sea}}(\mathbf{r}) = \frac{i}{2\pi} \int \bar{f}(E)(G - G^{\dagger})dE, \tag{3}
$$

$$
\hat{\rho}_F(\mathbf{r}) = \frac{eV}{4\pi} \int \left(-\frac{\partial \bar{f}}{\partial E} \right) G(\Gamma_L - \Gamma_R) G^{\dagger} dE, \qquad (4)
$$

where \bar{f} is the Fermi function with the unperturbed chemical potential, and only the linear term has been kept in (4). This separation is not unique and represents a convenient choice of gauge $[64]$. In the Fermi-sea contribution (3) , the bias enters through the linear potential drop. The Fermi-sea term can contribute to magnetization damping [\[55\]](#page-5-0).

We consider a Co/Pt bilayer with six monolayers each of Co and Pt. The atoms are placed on the sites of the ideal face-centered-cubic (fcc) lattice with the lattice parameter $a = 3.75$ Å, which is approximately halfway between those of fcc Co and Pt. The interface is taken along a (001) plane, and the current direction is [110]. The free surfaces are separated by four monolayers of empty spheres representing vacuum. The length of the active region is 120 monolayers, or 15.9 nm [\[55\]](#page-5-0).

The thin-film bilayers used for SOT measurements have rather large resistivities in the 20–100 $\mu\Omega$ cm range [\[30–32\]](#page-5-0), reflecting a large degree of disorder. The dominant types of defects responsible for the large residual resistivity are not known. As a generic representation, we use the Anderson disorder model, in which a random potential *Vi* with a uniform distribution in a range $-V_m < V_i < V_m$ is applied on each site *i*, including the empty spheres. In order to gain insight about the mechanisms of SOT and its dependence on the relaxation time τ , we considered four values of V_m : 0.77, 1.09, 1.33, and 1.54 eV; the corresponding resistivities range from 23 to $46 \mu \Omega$ cm [\[55\]](#page-5-0).

The total torque **T** is split into two parts: $\mathbf{T} = \mathbf{T}_e + \mathbf{T}_o$, which are, respectively, even and odd with respect to **m**. The crystallographic symmetry of the bilayer is C_{4v} . We align the \bar{x} axis with the current direction [110] and \bar{z} with [001], which is normal to the film plane. Group-theoretical analysis gives the allowed terms in the angular dependence of SOT:

$$
\mathbf{T}_e = P(\{A\}, \theta) \mathbf{m} \times [(\mathbf{z} \times \mathbf{E}) \times \mathbf{m}] + P(\{A'\}, \theta)(\mathbf{m} \cdot \mathbf{E})\mathbf{z} \times \mathbf{m}
$$

+ $P(\{A_\alpha\}, \theta)m_z(m_x^2 - m_y^2)\mathbf{m} \times (E_x, -E_y, 0) + P(\{A_\beta\}, \theta)[(m_x^2 - m_y^2)(\mathbf{m} \times \mathbf{z})(E_x m_x - E_y m_y) - \langle \dots \rangle] + \cdots,$ (5)

$$
\mathbf{T}_o = P(\{B\}, \theta)(\mathbf{z} \times \mathbf{E}) \times \mathbf{m} + P(\{B'\}, \theta)(\mathbf{m} \cdot \mathbf{E})\mathbf{m} \times (\mathbf{z} \times \mathbf{m}) + P(\{B_\alpha\}, \theta)(m_x^2 - m_y^2)\mathbf{m} \times (E_y, E_x, 0) + \cdots.
$$
 (6)

 Γ

Here $\{X\}$ denotes a set of coefficients X_{2n} , $n = 0, 1, \ldots$, and $P({X}, \theta) = \sum_{n} X_{2n} P_{2n}(\cos \theta)$ is a linear combination of even Legendre polynomials. The A , A' , B , and B' terms are allowed in a system with axial symmetry group $C_{\infty v}$, while the A_{α} , A_{β} , and B_{α} terms appear once the symmetry is reduced to C_{4v} . A_0 and B_0 represent the conventional dampinglike and fieldlike SOT terms, respectively.

The brackets $\langle \cdots \rangle$ in Eq. (5) stand for the average of the preceding term over the axial rotations of the bilayer (which is proportional to a linear combination of *A'* terms). Such averages already vanish for the A_{α} and B_{α} terms. In the axially symmetric polycrystalline sample with (001) texture, the predicted angular dependence is given by the *A*, *A* , *B*, and B' terms only.

In all calculations we have $\mathbf{E} = E\hat{x}$, and the torquances are defined as $\tau_e = \frac{T_e}{(ME)}$, $\tau_o = \frac{T_o}{(ME)}$, where *M* is the total magnetization, and have the dimension of a magnetoelectric coefficient $[B/E] = \text{ns/m} = \text{T nm/V}$.

The contribution of SOT to magnetization damping α , which is obtained in ferromagnetic resonance (FMR) linewidth measurements [\[32\]](#page-5-0), is $\Delta \alpha = C(E/B)$, where

$$
C = \mathbf{m} \cdot \nabla_{\mathbf{m}} \times [\mathbf{m} \times \boldsymbol{\tau}(\mathbf{m})] \tag{7}
$$

is the negative curl of the effective field [\[55\]](#page-5-0).

The Fermi-sea term is calculated in the middle of the device with a finite bias of order 1 mV applied symmetrically, as required by Eqs. (3) and (4), without disorder.

Equilibrium torque from the magnetic anisotropy is removed by subtracting the torque at positive and negative bias. To avoid the formidable task of evaluating the integral in Eq. (3), the Fermi-sea term is calculated at a finite temperature, using the integration method of Ref. [\[65\]](#page-5-0). The integrand only needs to be calculated at a finite number of points on the imaginary axis, most of which allow a coarse mesh in the reciprocalspace integral. The Fermi-sea term, which is strictly even, is calculated for 61 orientations of the magnetization [\[66\]](#page-5-0) and then fitted to Eq. (5). We have verified that the Fermi-sea torque depends linearly on the bias voltage, is insensitive to the length of the active region at constant field, and vanishes if the linear potential drop is replaced by two abrupt steps at the edges of the active region.

The Fermi-sea torquances obtained for $T = 50$, 100, 200, and 300 K are shown in Fig. [1.](#page-2-0) The minimal set of terms giving an acceptable fit at all temperatures includes A_0 , A_2 , A'_0 , and $A_{\beta 0}$ (see Table [I\)](#page-2-0); a more accurate multiparametric fit is used to compute the parameter C shown in Fig. [1.](#page-2-0) A'_0 is the largest term in the minimal fit, and it becomes quite large at low temperatures. A_2 and $A_{\beta 0}$ are also important at lower T , although $A_{\beta 0}$ should average out in polycrystalline samples.

The integrand in Eq. (4) for the Fermi-surface term contains a delta function at zero temperature and needs to be calculated only near the Fermi level E_F . The temperature dependence of this term is determined primarily by *τ* rather than the temperature in the Fermi distribution function. The

FIG. 1. Fermi-sea contribution to the torquance τ_e (arrows) at (a) 50 K, (b) 100 K, (c) 200 K, and (d) 300 K. The intensity of red (blue) color shows the positive (negative) magnitude of the damping parameter C [Eq. (7)]. In each panel, the number on the bottom right gives the scale of an arrow with a length equal to the sphere radius, and the one on the top right gives the color map scale (both in ns*/*m).

 3^c

Fermi-surface contribution to the total torquance, summed up over all sites in the active region, is calculated for 32 orientations of the magnetization, which form 16 antiparallel pairs, and averaged over a sufficient number of disorder configurations [\[67\]](#page-5-0). The symmetric and antisymmetric parts of the torque are then fitted to Eqs. [\(5\)](#page-1-0) and [\(6\)](#page-1-0). Only A_0 , A'_0 , B_0 , and B_0^7 coefficients turned out to be sizable; they are listed in Table I. With the exception of A'_0 , all coefficients depend weakly on the transverse supercell size L_y , confirming the reliability of disorder averaging. The fitted expressions were used to evaluate the damping parameter *C*, and the results are displayed in Fig. [2](#page-3-0) for two strengths of disorder, $V_m = 0.77$ and 1.54 eV.

The Fermi-surface contribution to the even torquance is dominated by the simple dampinglike term *A*0. The leading contribution to damping from the even torquance is given by $C = -(2A_0 + A'_0)m_y$. Although the Fermi-surface part of A'_0 converges slowly with the transverse supercell size L_y , it is clear from Table I that its contribution to *C* is small compared to A_0 .

Table I shows that, as the disorder strength increases from 0.77 to 1.54 eV, the A_0 term remains essentially constant, while the resistivity and the resistance of the active region increase by more than a factor of 2 [\[55\]](#page-5-0). This shows that the dampinglike torquance A_0 depends weakly on τ . The magnitude of A_0 is consistent with experimental data $[68]$ for a Co/Pt bilayer with similar layer thicknesses, as well as with prior calculations using phenomenological broadening [\[47\]](#page-5-0). These observations suggest that dampinglike SOT in this bilayer is dominated by intrinsic band-structure effects.

In addition to the simple fieldlike B_0 term, the odd torquance contains a sizable B'_0 term of comparable

	$\cal E$	L_{y}	Fermi surface, V_m (eV)				Fermi sea, T (K)

TABLE I. Coefficients (ns/m) in the angular expansion of the spin-orbit torquance in the Co/Pt bilayer. L_y is the lateral supercell size in the units of $a/\sqrt{2}$ (only relevant for the Fermi-surface part). *E* is the energy; $E_{\pm} = E_F \pm 0.046$ eV.

30

FIG. 2. Fermi-surface contribution to the torquance (arrows): (a) *τ*_{*e*} at *V_m* = 0.77 eV, (b) *τ*_{*e*} at *V_m* = 1.54 eV, (c) *τ*_{*o*} at *V_m* = 0.77 eV, and (d) τ_o at $V_m = 1.54$ $V_m = 1.54$ $V_m = 1.54$ eV. The scales are indicated as in Fig. 1. Supercells with $L_y = 2$ were used for disorder averaging.

magnitude (see Table [I\)](#page-2-0); other terms are relatively small. This is in contrast to calculations based on phenomenological broadening $[47]$, where no terms beyond B_0 were found. The *B*⁰ coefficient decreases with increasing disorder strength, as expected for ISGE. However, the relatively large error bar for B_0 , which is evident from its dependence on L_v , does not allow us to predict its temperature dependence at constant current density.

The mechanisms of SOT are closely related to its temperature dependence through their dependence on relaxation time *τ* . The intrinsic dampinglike SOT is independent of *τ* at a fixed electric field, and hence it should be proportional to the resistivity $\rho(T)$ at a constant current density. Although the fieldlike SOT due to interfacial ISGE scales with *τ* similar to the conductivity, the interfacial and bulk scattering rates may be different.

There are few experimental measurements of the temperature dependence of SOT, and they are poorly understood. In Ta-based systems the fieldlike SOT was reported to increase quickly with temperature while the resistivity and the dampinglike SOT are nearly constant [\[69,70\]](#page-5-0). This behavior is inconsistent with the ISGE mechanism of the fieldlike SOT. Temperature dependence of the fieldlike SOT is different in as-grown Pt/Co and annealed Pt/CoFeB bilayers [\[71\]](#page-5-0). The unexpected temperature dependence of the fieldlike SOT suggests that processes involving phonons or magnons may play an important role [\[1](#page-4-0)[,72\]](#page-5-0).

The terms B'_0 and B_2 in the odd torquance contribute to damping as $C = 3(B'_0 + B_2)m_x m_z$, which is the "planar Halllike" damping observed when **m** lies in the *xz* plane [\[32\]](#page-5-0). Table [I](#page-2-0) shows that the term B'_0 is not sensitive to disorder strength, similarly to A_0 . The B_2 term was found to be small in all cases.

FIG. 3. Atom-resolved torquances in the Co(6)Pt(6) bilayer (solid lines) and in the freestanding Co(6) film (dashed lines) at $V_m = 1.09$ eV, obtained with $L_y = 3$. (a) Even terms A_0 and A'_0 and (b) odd terms B_0 and B'_0 . Light-blue curves (labeled $\xi_{Pt} = 0$): A_0 in Co(6)Pt(6) with SOC on Pt atoms set to zero, obtained with $L_v = 1$.

The existence of large terms beyond B_0 in the odd SOT is consistent with experimental observations [\[30–32\]](#page-5-0). However, while we found large B'_0 and $B_2 \approx 0$ in a Co/Pt bilayer, measurements of SOT in AlO*^x /*Co*/*Pt [\[30\]](#page-5-0) and AlO*^x /*Co*/*Pd [\[31\]](#page-5-0) suggest an approximate relation $B_2 = -\frac{2}{3}B'_0$ in these systems [\[55\]](#page-5-0). The relative magnitude of the damping parameter *C* measured in the *xy* (spin-Hall-like SOT) and *xz* planes (planar Hall-like SOT) agrees with FMR linewidth measurements [\[32\]](#page-5-0), but the sign of B_0 ['] is different. This disagreement may be due to the inadequacy of the Anderson disorder model. Indeed, weak dependence of B_0 ['] on disorder strength (see Table [I\)](#page-2-0) and the absence of any terms beyond B_0 in calculations based on band broadening [\[47\]](#page-5-0) suggest that these terms arise from vertex corrections, which are sensitive to the type of disorder present in the system.

Table [I](#page-2-0) also lists the Fermi-surface SOT coefficients calculated at energies $E_{+} = E \pm 0.046$ eV, where $\left(-\frac{\partial \bar{f}}{\partial E}\right)$ is reduced by 50% compared to its maximal value at 300 K. Weak energy dependence of A_0 and B'_0 , and approximately linear dependence of B_0 , suggests that these coefficients are not sensitive to the Fermi temperature. The A'_0 coefficient remains small.

For further insight into the origin of SOT, Fig. 3 shows atom-resolved contributions to the A_0 , A'_0 , B_0 , and B'_0 terms at $V_m = 1.09$ eV. For comparison, these quantities are also

shown for the freestanding six-monolayer Co film with the same lattice parameter, where the total torquance vanishes by symmetry.

The contributions to A_0 and B_0 are spread throughout the thickness of the film, with the largest contributions coming from the Co atoms at the Co/Pt interface and at the free surface of Co. On the other hand, the B'_0 term appears to originate at the Co/Pt interface. It is interesting to observe a considerable contribution to B_0 from the Pt atoms near the interface, which carry a magnetic moment of about $0.24\mu_B$ thanks to the magnetic proximity effect [\[73\]](#page-5-0). In fact, the SOT on the Pt atoms contributes as much as 40% of the total magnitude of *B*0. Surprisingly, the atom-resolved contributions at the surface Co atoms in the freestanding Co film are even larger in magnitude than those at the Co/Pt interface.

Finally, we examine the SOT with the SOC on Pt atoms switched off, using the supercell with $L_y = 2$. The A_0 term essentially disappears, but, as seen in Fig. $3(a)$, atom-resolved contributions remain sizable, and those near the free Co surface barely change. The B'_0 term is strongly suppressed from −7*.*6 to −1*.*4 ns*/*m, which is comparable to the averaging error. On the other hand, the B_0 term increases to -10.8 ns*/*m, with strongly redistributed atom-resolved contributions [Fig. $3(b)$]. These results suggest that, without SOC on Pt, the SOT in our Co/Pt bilayer is nearly nondissipative, i.e., it does not affect magnetization damping. Current-induced Dzyaloshinskii-Moriya interaction [\[74\]](#page-5-0) formally leads to

dampinglike atom-resolved torques that add up to zero [\[55\]](#page-5-0). Thus, strong fieldlike SOT does not require a heavy-metal layer, but understanding the prerequisites for observing dampinglike SOT without heavy metals [\[75\]](#page-5-0) will require further research.

In conclusion, we have demonstrated the feasibility of calculating the SOT for a Co/Pt bilayer with an explicit model of disorder within the NEGF formalism based on densityfunctional theory. Terms beyond the usual dampinglike and fieldlike torques were found, including a sizable planar Halllike B'_0 term [Eq. [\(6\)](#page-1-0)], consistent with FMR measurements [\[32\]](#page-5-0). The dissipative part of SOT is almost entirely due to SOC on Pt atoms.

We thank Vladimir Antropov, Gerrit Bauer, Ilya Krivorotov, Farzad Mahfouzi, Branislav Nikolic, Yaroslav ´ Tserkovnyak, and Igor Žutic for useful discussions. The work ´ at UNL was supported by the National Science Foundation (NSF) through Grant No. DMR-1609776 and the Nebraska Materials Research Science and Engineering Center (MR-SEC; Grant No. DMR-DMR-1420645). A.K. was supported by the US Department of Energy, Office of Science, Basic Energy Sciences, under Award No. DE-SC0014189. M.v.S. was supported by the EPSRC CCP9 Flagship Project No. EP/M011631/1. Calculations were performed utilizing the Holland Computing Center of the University of Nebraska, which receives support from the Nebraska Research Initiative.

- [66] The 61 pairs of points on the sphere include 12 vertices, 20 face centers, and 30 edge centers of an icosahedron, plus 60 vertices of a buckyball.
- [67] Because the terms in Eq. [\(4\)](#page-1-0) with Γ_L and Γ_R give identical contributions to the odd torquance, it is advantageous to average these terms independently over different disorder configurations.
