(Received 8 April 2023; revised 31 July 2023; accepted 27 September 2023; published 27 November 2023)

New <sup>53</sup>Cr solid-state NMR measurements are presented for Cr<sub>2</sub>N, CrB<sub>2</sub>, CrO<sub>2</sub>, Cr<sub>2</sub>O<sub>3</sub>, (NH<sub>4</sub>)<sub>2</sub>CrO<sub>4</sub>, and BaCrO<sub>4</sub>. Measurements of the <sup>53</sup>Cr nuclear quadrupole coupling constants, asymmetry parameters, and chemical (Knight) shifts of chromium compounds provide important experimental data for the validation of quantum chemistry calculations. In this work, natural abundance <sup>53</sup>Cr magnetic resonance, at 9.4 T, is used to examine the metals  $Cr_2N$  and  $CrB_2$  as well as the diamagnetic insulating chromates  $(NH_4)_2CrO_4$  and  $BaCrO_4$  at room temperature. <sup>14</sup>N and <sup>11</sup>B NMR spectra are also obtained at room temperature for Cr<sub>2</sub>N and CrB<sub>2</sub>, respectively. The shift observed from  $CrB_2$  is believed to be the largest Cr(0) Knight shift (-9982 ppm) for any chromiumcontaining metallic material. <sup>53</sup>Cr measurements in zero applied magnetic field as a function of temperature are reported for ferromagnetic CrO<sub>2</sub> and antiferromagnetic Cr<sub>2</sub>O<sub>3</sub>. Within experimental accuracy the magnetization behavior in CrO<sub>2</sub> is modeled using Bloch spin-wave theory, where the magnetization decreases as  $T^{3/2}$  over temperatures from 4.2 to 295 K, which also appears to adequately model the sublattice magnetization of Cr<sub>2</sub>O<sub>3</sub>. These new experimental results are put into the context of previous magnetic resonance results found in the literature by providing the first comprehensive tabulation of such <sup>53</sup>Cr magnetic resonance data from solids for over 50 years. The low-temperature zero applied magnetic field central frequencies are correlated with valence state, and spin stiffness has been calculated for 16 chromium compounds. A knowledge of these parameters will enable further progress in using <sup>53</sup>Cr magnetic resonance as a probe of electronic and magnetic structures, thereby contributing to the more systematic development of novel materials.

DOI: 10.1103/PhysRevMaterials.7.114410

# I. INTRODUCTION

<sup>53</sup>Cr NMR studies of solid chromium-containing compounds were first reported in the 1960s as research teams sought to unravel the nature of the bonding in antiferromagnetic and ferromagnetic materials and to test theoretical schemes for approximating the nature of magnetic ordering [1–5]. With the current level of interest in quantum materials, for applications in spintronics and as topological insulators, the challenge of understanding, predicting, and controlling magnetic properties and quantum states in Cr compounds has reinvigorated <sup>53</sup>Cr NMR studies [6–8]. The literature of relevance to the compounds studied here for the first time is introduced, followed by a report of new measurements of <sup>53</sup>Cr NMR at 9.4 T and in zero applied field with <sup>53</sup>Cr in natural abundance. These new results are compared with the literature where the ability to understand the valence and magnetic environment are highlighted. A key aim here is to provide a comprehensive overview of the literature on <sup>53</sup>Cr magnetic resonance from 1961 to date. The implications for the trends in these data and the ability to probe bonding and spin properties for correlation with other materials properties (e.g., magnetization and spin density) are examined. Suggestions for future work are highlighted throughout the results and discussion.

# II. STATE OF THE ART OF MAGNETIC RESONANCE OBSERVATION OF CHROMIUM IN SOLIDS

The first report of solid-state <sup>53</sup>Cr (I = 3/2, natural abundance 9.5%) NMR was in ferromagnetic CrBr<sub>3</sub> by Gossard et al. [1]. The NMR line shape could be obtained in zero applied field because of the existence of a strong internal magnetic hyperfine field at the Cr nucleus at temperatures below the ferromagnetic Curie point temperature  $T_{\rm C} = 37$  K. Using the internal field in materials with spontaneous magnetization to observe the magnetic resonance signal is termed zero-field NMR or ferromagnetic nuclear resonance. The temperature dependence of the <sup>53</sup>Cr resonance was measured from 1.34 to 4.2 K, and the data were fitted with spin-wave theory [9–11]. These <sup>53</sup>Cr NMR results were the first experimental test of spin-wave theory for a ferromagnetic compound using NMR. Three months after the Gossard *et al.* report [1], Narath [2] reported the first zero field <sup>53</sup>Cr NMR in an antiferromagnetic compound, CrCl<sub>3</sub> (Néel temperature,  $T_N = 16.8$  K) measured

<sup>\*</sup>Deceased.

<sup>&</sup>lt;sup>†</sup>anita.hill@csiro.au

<sup>&</sup>lt;sup>‡</sup>m.e.smith@soton.ac.uk

from 1.23 to 4.02 K, providing data for a further test of spin-wave theory. The ferromagnet CrI<sub>3</sub> ( $T_{\rm C} = 68$  K) was subsequently characterized using <sup>53</sup>Cr zero-field NMR as a low-temperature test of spin-wave theory [3]. Anisotropic Cr orbital states form a current topic of materials research interest for spintronic devices, and as such the chromium trihalides are still under investigation experimentally and theoretically as 2D materials with intrinsic ferromagnetic and antiferromagnetic properties [12,13].

Rubinstein *et al.* [14] studied <sup>53</sup>Cr in antiferromagnetic  $Cr_2O_3$  in zero applied field using powder samples with <sup>53</sup>Cr in natural abundance and enriched. For measurements at 1.6 K, the central line was detected at 70.43 MHz with the satellite transitions lying  $262 \pm 10$  kHz to either side, yielding a quadrupolar frequency  $v_Q$  of 0.525 MHz and a quadrupole coupling constant  $C_Q$  of 1.05 MHz for  $Cr_2O_3$  ( $v_Q$  and  $C_Q$  defined in Sec. IV A). The central-line resonance frequency was reported as constant within the accuracy of the measurement over the temperature range studied from 1.6 to 16 K. To date, no one has reported <sup>53</sup>Cr NMR measurements of  $Cr_2O_3$  at temperatures much above liquid helium temperature. Internal-field magnetic resonance data are reported in the present work, significantly extending the temperature range.

The first report of <sup>53</sup>Cr NMR in ferromagnetic CrO<sub>2</sub> was in 1963 by Yasuoka et al. [15], who detected a single peak at 36.14 MHz in zero field at 77 K with the weak signal disappearing above 240 K. A later study [16] at 4.2 K and zero applied field reported two <sup>53</sup>Cr peaks at 26.3 and 36.7 MHz, even though a single chromium site is expected in the rutile structure of stoichiometric highly crystalline CrO<sub>2</sub>; the authors tentatively attributed the high-frequency line to the expected single Cr site and the low-frequency line to Cr atoms affected by vacancies. The origin of these two <sup>53</sup>Cr sites has continued to be the subject of study. In 2007 Shim et al. [17] showed that the sites could not be due to vacancies, nor could they be due to Cr sites in domains and domain walls. Much recent work has been reported on <sup>53</sup>Cr in CrO<sub>2</sub> due to renewed interest in anomalous electronic states of half-metallic chromium oxides [18–21], with the most robust recent attribution of the two sites to an electronic state caused by local orbital order [18–20].

<sup>53</sup>Cr NMR measurements in numerous diamagnetic chromates have been reported with nuclear quadrupolar coupling constants, C<sub>Q</sub>, ranging from 1.17 to 5.01 MHz for 11 chromates and 7.25 to 8.28 MHz for 2 dichromates [22–24]. The <sup>53</sup>Cr chemical shift range reported in diamagnetic alkali-earth chromate and dichromate compounds is -117 to +188 ppm attributed to the small shielding anisotropies expected for  $d^{\circ}$ Cr(VI) complexes [22,25]. Nowak and co-workers [26,27] have reported <sup>53</sup>Cr NMR in hexagonal and cubic chromium hydrides, establishing these compounds as metals (Pauli paramagnets) and reporting the temperature-independent Knight shift for each phase. Barnes and Graham determined the Knight shift in pure Cr metal in the paramagnetic state above  $T_{\rm N} = 313$  K and at 300 K in  $Cr_{1-x}V_x$  alloys with up to 3 at. % V [4]. Kontani [28] reported <sup>53</sup>Cr NMR for the  $Cr_{1-x}Mo_x$ system with x varying from 0.25 to 26.3 at. %. Although there are several important Cr-containing stoichiometric compounds that are metals, e.g., the chromium boride refractory metals and the chromium nitrides, to date there has been very little <sup>53</sup>Cr NMR reported in metals and alloys [29–31]. <sup>53</sup>Cr has a nuclear gyromagnetic ratio,  $\gamma$ , of -2.406 MHz/T which is low [29], and <sup>53</sup>Cr is not the most favored of the low- $\gamma$ nuclides for solid-state NMR, sometimes being referred to as exotic, miscellaneous, unreceptive, and difficult. However, it has been shown in recent years that a combination of relatively large samples and, for wide lines, techniques such as frequency stepping can aid in the observation of low- $\gamma$ nuclei [24,29,30,32], helping to overcome the challenges of low sensitivity, low natural abundance, and broad resonance lines. This study encompasses a wide range of samples, some of which will have high internal magnetic fields or large Knight shifts that can produce a large fluctuating spin density/magnetic field at the  ${}^{53}$ Cr site resulting in short- $T_1$  relaxation times. In other samples, (e.g., nonmagnetic insulating samples) the relaxation can be significant slower. Typically, the recycle delays were set to produce relaxed or partially relaxed spectra tailored to the sample. In most samples fast relaxation occurs so a repetition time of 20-100 ms was used. The ability to recycle quickly for most samples means spectra can be rapidly collected helping the observation, especially when frequency-stepping strategies are adopted to locate the resonances by looking over a large frequency range. In addition, for ferro- and ferrimagnetic samples, enhancement mechanisms related to the way the electronic magnetization responds to the applied rf field can lead to a very significant additional boost to the magnitude of the signal [33,34].

#### **III. EXPERIMENTAL DETAILS**

CrO<sub>2</sub> and CrB<sub>2</sub> powders (99% purity), Cr<sub>2</sub>O<sub>3</sub> and BaCrO<sub>4</sub> powders (purity  $\geq 98\%$ ), and (NH<sub>4</sub>)<sub>2</sub>CrO<sub>4</sub> powder (98%) purity) were obtained from Sigma-Aldrich. Industrial-grade Cr<sub>2</sub>N powder (92% purity) was obtained from Japan. Powder x-ray-diffraction (XRD) scans were measured using a Bruker D8 Advance spectrometer using Cu K $\alpha$  radiation to confirm crystallinity and purity. Analysis of the data was performed using the Bruker XRD search match program EVA<sup>TM</sup>4.2. Differential scanning calorimetry (DSC) was performed on 10 mg of the Cr<sub>2</sub>O<sub>3</sub> powder using a Mettler Toledo DSC 2 at a heating rate of 10 K/min from 133 to 373 K in flowing nitrogen (40 mL/min). Analysis of the data was performed using the STAR<sup>e</sup> software. A Zeiss Merlin field-emission scanning electron microscope (SEM) was used to acquire images of the  $CrO_2$  powder at an accelerating voltage of 3 kV and 100000× magnification.

High-field (9.4 T) and zero applied field NMR spectroscopy were performed using a Bruker Avance 400 spectrometer to generate the pulses and detect the signal via a phase-cycled two pulse-echo sequence using a pulse duration of ~4 to 10  $\mu$ s, pulse separation of ~50  $\mu$ s, and pulse repetition time of 20 to 500 ms depending on nuclear relaxation rate. The Larmor resonance frequencies for the investigated nuclei <sup>11</sup>B, <sup>14</sup>N, and <sup>53</sup>Cr at  $B_0 = 9.4$  T are 128.40, 28.91, and 22.66 MHz, respectively. The reference <sup>11</sup>B NMR zero line shift was set using NaBH<sub>4</sub> in dilute aqueous solution, the reference for <sup>14</sup>N was solid NH<sub>4</sub>Cl, and the reference for <sup>53</sup>Cr was (NH<sub>4</sub>)<sub>2</sub>CrO<sub>4</sub> in saturated aqueous (D<sub>2</sub>O) solution. For CrO<sub>2</sub>, small low-power 1- $\mu$ s pulses were used since the signal strength is boosted by the inter- and intradomain signal-enhancement mechanism in ferromagnets described elsewhere [33,34]. There was not a systematic determination here of the enhancement factor, although for <sup>53</sup>Cr, in the core domains (as opposed to the domain walls) where it is reported in the papers summarized here, the enhancement factor is usually in the range 10-100 and typically around 30. The probe bandwidth was approximately 800 kHz [full width at half maximum (FWHM) of the tuning curve]. The <sup>53</sup>Cr zero field NMR lines were recorded at 77, 195, and 295 K at an operating frequency adjusted to put the line maximum at the center of the frequency range. Frequency-stepped spectra [32] for <sup>53</sup>Cr were obtained at 295 K for CrB<sub>2</sub> and Cr<sub>2</sub>N at 9.4 T and at 77 and 195 K in zero field for Cr<sub>2</sub>O<sub>3</sub>. For the lines defined by frequency stepping, the width of the pulses was varied to achieve the pulse bandwidth for the chosen frequency slice: typically, 5 µs for a 200-kHz slice using 300-W transmitter power. For  $Cr_2O_3$  higher-power 5-µs pulses were necessary since the signal-enhancement mechanism that operates for ferromagnets is not applicable to antiferromagnets. The probe head was an 8-cm-long cylindrical copper pot with an enameled wire wound coil attached to a home-built matching circuit by a short, low thermal conductivity, transmission line [35].

#### **IV. RESULTS AND DISCUSSION**

# A. Hyperfine interactions

Hyperfine interactions experienced by a nucleus act as fingerprints of the different atomic sites in materials. In the case of the compounds examined here, the parameters determined by magnetic resonance measurements provide a sensitive probe of the local and magnetic structure around the <sup>53</sup>Cr atomic sites. The interactions experienced by a <sup>53</sup>Cr nucleus include quadrupolar via electric-field gradients (efgs), shielding (either chemical shift from conventional localized electronic bonding or Knight shift from delocalized conduction electrons), and for electronic magnetism, the local internal field [29,30,33,34]. An atomic nucleus with spin I > 1/2 has an electrical quadrupole moment which interacts with any efg, whose largest component  $V_{zz}$  (J/Cm<sup>2</sup>) is defined as

$$V_{zz} = \partial^2 V / \partial z^2, \tag{1}$$

Simulation of the line-shape features can give the nuclear quadrupole coupling constant,  $C_Q$ , in units of frequency and asymmetry parameter  $\eta$ , defined as

$$C_{\rm Q} = eQV_{zz}/h \quad \text{and} \quad \eta = (V_{xx} - V_{yy})/V_{zz}, \tag{2}$$

where Q is the quadrupole moment of the nucleus in units m<sup>2</sup>, e is the electron charge in units of coulombs (C), h is Planck's constant, and  $V_{ii}$  are the respective efg tensor components. In highly crystalline, well-ordered samples the resulting powder line shapes of all transitions will be structured with clear peaks and singularities from which the quadrupolar interaction parameters can be extracted [29,30]. Often such structure cannot be observed, in which case the second-order perturbed central linewidth  $\Delta$  (FWHM) can be used to estimate  $C_Q$  via [29,30]

$$\Delta = \left[25(\nu_Q^2)/144\,\nu_L\right][I(I+1) - 3/4],$$
  
where  $\nu_Q = 3C_Q \left\{\sqrt{[1 + (\eta^2/3)]}/[2I(2I-1)],$  (3)

and where  $v_L$  is the Larmor frequency. The value of  $C_Q$  from experiment can be compared with the  $V_{zz}$  calculated from density-functional theory (DFT). This combination of spectroscopic measurement and quantum chemistry calculations of quadrupole parameters provides a powerful means to study the solid state (see for example Bastow *et al.* [36]).

Recently, DFT methods have also been used to calculate the magnetic shielding or hyperfine-induced shift of the nuclear resonance (Knight shift, KS) in elemental metals [37] using the WIEN2K program [38] where both orbital and spin contributions are needed for the transition metals. For <sup>53</sup>Cr in pure Cr metal, the theoretical KS of 6818 ppm is in excellent agreement with the experimental KS of 6870  $\pm$  100 ppm [4,37]. Where possible in this study, measured values for  $C_Q$ and chemical (Knight) shift are compared to DFT predictions for these values. For Cr compounds with spontaneous magnetization, the Knight shift (in %) is related to the Pauli-spin susceptibility  $\chi_P$  per Cr atom (in cm<sup>3</sup>/mol) by

$$KS = [A][\chi_P/(N_A \mu_B)], \qquad (4)$$

where A is the hyperfine coupling constant in  $T/\mu_B$ ,  $N_A$  is Avogadro's number  $6.022 \times 10^{23} \text{ mol}^{-1}$ , and  $\mu_B = 9.27 \times 10^{-24} \text{ J/T}$ .

When there are unpaired electrons then an internal magnetic field is generated and usually no magnetic field needs be applied. The zero-field (zf)-applied NMR center-line resonance,  $v_{zf}$ , (in units of MHz) is a measure of the hyperfine field at the <sup>53</sup>Cr nucleus,  $B_{\rm hf}$  (in units of T) through the relationship

$$B_{\rm hf} = \nu_{\rm zf} / {}^{53} \gamma, \qquad (5)$$

where  ${}^{53}\gamma$  is the gyromagnetic ratio of the  ${}^{53}$ Cr nucleus (in units of MHz/T). At 0 K,  $v_{zf}(0)$  is related to the local magnetic moment at 0 K, M(0). The high-field approximation is made here because the local field is the dominant determinant of the observed frequency. Other interactions can make small perturbations to the zero-field frequency position [39]. The ground-state magnetic moment M can be estimated from the spin-only contribution from the number, n, of unpaired electrons,  $M = \sqrt{n(n+2)}$  or estimated as the average magnetic moment through the Landé g factor for the ion ground state with

$$M = g\mu_{\rm B}S,\tag{6}$$

where S = n/2 is the spin, and  $\mu_B$  is the Bohr magneton per Cr ion ( $\mu_B/Cr$ ), and *M* can be directly measured using neutron diffraction or magnetometry. The <sup>53</sup>Cr Landé *g* factor for ground-state ions can be estimated from electron spin-resonance measurements within ~4% as 2 [40]. NMR measurements as the temperature approaches 0 K (liquidhelium temperatures) in zero field are necessary to minimize thermal effects on the value of the hyperfine constants derived from the data and for comparison with quantum chemical calculations of hyperfine interactions. The sublattice magnetization and  $\nu_{zf}$  will decrease as the temperature rises due to thermally excited spin waves. The relationship between the <sup>53</sup>Cr  $\nu_{zf}$  near 0 K and the magnetic moment *M* near 0 K in  $\mu_B$ per Cr ion can be described by

$$\nu_{\rm zf}(0) = {}^{53}\gamma |A| M(0), \tag{7}$$

FIG. 1. Experimental (top) and simulated (bottom) central (1/2, -1/2) transition static <sup>53</sup>Cr NMR line shapes for static powder samples of  $(NH_4)_2$ CrO<sub>4</sub> (left) and BaCrO<sub>4</sub> (right) at 9.4 T. Intensity values are shifted on *y* axis for clarity.

where |A| is the absolute value of the hyperfine coupling constant in  $T/\mu_B$ . The gyromagnetic ratio of the <sup>53</sup>Cr nucleus, <sup>53</sup> $\gamma$  in MHz/T, is a constant. The absolute value of the hyperfine coupling constant, |A|, depends on the configuration and valence of the Cr ion in the compound, which is discussed in Sec. IV G 1.

# B. (NH<sub>4</sub>)<sub>2</sub>CrO<sub>4</sub> and BaCrO<sub>4</sub>

Alkali-metal chromates and alkaline-earth metal chromates have four Cr-O bonds of nearly equal length giving slightly distorted tetrahedral coordination of the Cr in the oxochromate (VI) anions,  $CrO_4^{2-}$ . This configuration restricts the magnitude of the efg at the Cr site, such that the coupling constant for the electric hyperfine interaction,  $C_Q$ , at the Cr site is typically less than 10 MHz [22]. In this circumstance the electric hyperfine interaction can be conveniently measured by conventional high applied field <sup>53</sup>Cr NMR via a simulation of a second-order perturbed line shape [39] which yields  $C_0$  and  $\eta$  [Eq. (2)], where  $\eta$  measures the departure from axial symmetry of the efg tensor [29]. Ammonium chromate  $(NH_4)_2$ CrO<sub>4</sub> is monoclinic with space group C2/m, [41] while barium chromate BaCrO<sub>4</sub> is orthorhombic with space group Pnma [42]; both compounds have no electronic magnetic moment and no magnetic ordering.

Sharply defined <sup>53</sup>Cr NMR spectra are presented for (NH<sub>4</sub>)<sub>2</sub>CrO<sub>4</sub> and BaCrO<sub>4</sub> obtained at 9.4 T, along with DMFIT [43] simulations of the central transition based on secondorder quadrupole perturbation theory, in Fig. 1. The <sup>53</sup>Cr spectrum for (NH<sub>4</sub>)<sub>2</sub>CrO<sub>4</sub> has not been previously reported although a preliminary value for  $C_{\rm O}$  of ~2.5 MHz was mentioned in earlier work [44]. The values obtained here for  $C_{\rm O}$  and  $\eta$  in BaCrO<sub>4</sub> are in excellent agreement with parameters reported at higher fields as shown in Table I. In these crystalline diamagnetic compounds, the central (1/2,-1/2) <sup>53</sup>Cr NMR transition displays relatively sharp singularities enabling accurate measurement of  $C_0$ ,  $\eta$ , and isotropic chemical shift  $\delta_{iso}$  from the second-order quadrupolar features. The resulting isotropic chemical shift  $\delta_{iso} = 0$  ppm for both chromates, with the reference zero shift obtained from (NH<sub>4</sub>)<sub>2</sub>CrO<sub>4</sub> in aqueous solution, is in good agreement with the previously reported value of  $\delta_{iso} = 1750 \pm 20$  ppm for BaCrO<sub>4</sub> powder determined under magic-angle spinning and referenced to Cr(CO)<sub>6</sub> in chloroform solution known to be shifted -1797 ppm relative to the CrO<sub>4</sub><sup>2-</sup> used here [44,45]. Buhl [45] has calculated the chemical shift for CrO<sub>4</sub><sup>2-</sup> using two density functionals and has reported values of 21 and 81 ppm as compared to the experimental value of 0 ppm.

### C. Cr<sub>2</sub>N

Cr<sub>2</sub>N is an interstitial compound showing metallic behavior and no magnetic transitions; its principal use is as a tempering agent in steel making. The crystal structure is trigonal [46] with a single Cr site (fully occupied) with no axis of symmetry. The powder XRD pattern [35] indicates a well-crystallized specimen with minor impurity phases of  $CrN_{0.98}$  (6 ± 1%) and Cr (1.6 ± 0.9%). It may be noted in passing that monochromium nitride, CrN, is an insulator at room temperature and an antiferromagnetic metal below the Néel temperature of 286 K [47]. *Ab initio* DFT calculations for two-dimensional Cr<sub>2</sub>N *MX*ene have predicted an antiferromagnetic metal [48].

The <sup>53</sup>Cr and <sup>14</sup>N NMR spectra for Cr<sub>2</sub>N are reported here for the first time. There exists a relatively substantial electric quadrupole interaction at the Cr site. The <sup>53</sup>Cr NMR spectrum [Fig. 2(a)] at a magnetic field of 9.4 T has a width of approximately 300 kHz and a Knight shift of -1900 ppm. It was not possible to capture the spectrum using standard (echo) pulsed NMR at a single operating frequency. The strategy employed here, and subsequently for the Cr<sub>2</sub>O<sub>3</sub>, was to record the amplitude using a frequency-stepped echo approach [32]. Simulation of the spectrum using DMFIT [43] gives  $C_Q = 6.3 \pm 0.2$  MHz and  $\eta = 0.15 \pm 0.10$ .

The crystal structure [46] also indicates four N sites–one unoccupied, one fully occupied, and two partially occupied– however, a static pulsed <sup>14</sup>N NMR spectrum [Fig. 2(b)] of the specimen indicates a single line with 35-kHz width (FWHM) and a small negative shift  $\delta_{iso} = -200$  ppm. The single narrow <sup>14</sup>N NMR line is somewhat surprising considering (i) the site symmetry of all the N sites is no higher than  $\overline{3}$ , and (ii) <sup>14</sup>N (I = 1) is one of few quadrupolar nuclei with integer spin,

Compound	$C_{\rm Q}~({\rm MHz})$	η	Field strength (T)	Reference
$(NH_4)_2CrO_4$	$3.1 \pm 0.1$	$0.58 \pm 0.05$	9.4	Present work
$(NH_4)_2 CrO_4$	$\sim 2.5$	Not reported	7.05 or 9.4	[44]
BaCrO <sub>4</sub>	$4.9 \pm 0.1$	$0.16 \pm 0.05$	9.4	Present work
BaCrO <sub>4</sub>	$5.0\pm0.05$	$0.14\pm0.03$	11.75 and 18.8	[22]

TABLE I. <sup>53</sup>Cr quadrupolar coupling constant  $C_Q$  and asymmetry parameter  $\eta$  for  $(NH_4)_2CrO_4$  and BaCrO<sub>4</sub> measured at 9.4 T compared with values previously reported.

and in noncubic environments exhibits a first-order broadened <sup>14</sup>N NMR line shape [39]. The observed line possibly originates from the one fully occupied site. This single line may be due to vacancy-assisted mobility of the nitrogen atoms, meaning that only the permanently filled site will be detected. Low-temperature NMR measurements may shed light on the origin of the <sup>14</sup>N line shape and are suggested as future work. From our room-temperature line shape, an upper-limit value of  $C_0 < 0.047$  MHz can be estimated from the FWHM [49]. Bastow et al. [50] have previously reported <sup>14</sup>N  $C_Q$  values for other metal nitrides including AlN ( $C_{\rm Q} < 0.01$  MHz). For AlN the <sup>14</sup>N static spectrum was an approximately Gaussian line shape with FWHM of 7.5 kHz which gave the upperlimit  $C_Q$  value [(4/3)FWHM] of < 0.01 MHz. This work has recently been revisited in a single-crystal AlN specimen by Zeman *et al.* [51] reporting that  $C_Q = 8.19$  kHz; hence, this method is found to be robust for estimating an upper limit for  $C_{\rm O}$  within 20%.

# D. CrB<sub>2</sub>

CrB<sub>2</sub> has been established as a metal by single crystal measurements of (*inter alia*) electrical resistivity, Hall coefficient, and magnetic susceptibility [52] with weak itinerant antiferromagnetic ordering below the Néel temperature of 88 K [53]. The crystal structure [54] is hexagonal *P6/mmm* with Cr in 2a at (0,0,0) and B in 4d at (1/3, 2/3, 1/2), a = 2.969 Å, c = 3.006 Å, both sites having axial symmetry and  $\eta = 0$ . The powder XRD [35] shows well crystallized CrB<sub>2</sub> with Cr<sub>3</sub>B<sub>4</sub> detected as a minor impurity.

The  ${}^{53}$ Cr NMR line shape for CrB<sub>2</sub> has not been previously reported. In the present work, frequency-stepped  ${}^{53}$ Cr NMR

was used to delineate the line shape for CrB<sub>2</sub> at 295 K: a single, narrowly peaked, somewhat asymmetric line shape (FWHM = 38 kHz) [Fig. 3(a)] exhibiting a very large negative Knight shift:  $K_{iso} = -9982$  ppm (-226 kHz at 9.4 T). There is no second-order quadrupolar structure with distinct singularities of the central transition, suggesting a relatively small  $C_0$ . However, attributing the observed, relatively narrow <sup>53</sup>Cr linewidth to residual second-order quadrupolar broadening [Eq. (3)], with I = 3/2 and the Larmor frequency  $v_{\rm L} =$ 22.66 MHz at 9.4 T, yields an estimate for  $\nu_Q \approx 1.285$  MHz giving  $C_0 \approx 2.6 \pm 0.5$  MHz. This  $C_0$  value for <sup>53</sup>Cr compares reasonably well with the value of 3.05 MHz calculated ab initio by Schwarz et al. [55]. There is some broader underlying intensity observed which probably comes from the satellite transitions given this small  $C_0$ . The absence of a large quadrupolar interaction for <sup>53</sup>Cr is somewhat unexpected given the substantial nuclear quadrupole interaction exhibited at the metal sites by the isostructural neighboring group III and IV transition-metal diborides ScB2, TiB2, and  $ZrB_2$  [36], but the small  $C_Q$  estimated here for <sup>53</sup>CrB<sub>2</sub> is consistent with the *ab initio* calculation [55]. These other diborides have sharp features for the second-order perturbed central transition splitting at the metal site, and the first-order perturbed satellite singularities can also be readily observed allowing precise determination of  $C_{\rm O}$  values, significantly different from what is observed here for CrB<sub>2</sub>.

The  ${}^{53}\text{CrB}_2$  line shape has presumably gone undetected for decades due to the large negative Knight shift making it difficult to know where to search for the resonance. The Knight shift for pure Cr metal is large and positive, 6870 ppm [4]. Although the transition-metal monoborides and diborides formed the basis of substantial early work, the  ${}^{53}\text{Cr}$ 

FIG. 2. (a) Static <sup>53</sup>Cr NMR data from  $Cr_2N$  showing experimental (top) and simulated (bottom) central (1/2, -1/2) transition line shape. Intensity values are shifted on y axis for clarity. (b) Static <sup>14</sup>N NMR spectrum of  $Cr_2N$ .

FIG. 3. Static NMR data from  $CrB_2$  showing (a) central (1/2, -1/2) transition for <sup>53</sup>Cr and (b) central as well as first-order quadrupole broadened ( $\pm 3/2, \pm 1/2$ ) transition for <sup>11</sup>B.

resonance proved difficult to detect [56,57]. The present work may encourage <sup>53</sup>Cr NMR study of the bonding and electronic structure in the stable chromium borides, e.g.,  $Cr_2B$ ,  $Cr_5B_3$ , CrB,  $Cr_3B_4$ ,  $CrB_4$ , and  $CrB_2$  for comparison with theoretical predictions [58].

The <sup>11</sup>B NMR spectrum at 295 K exhibits a first-order quadrupolar line shape [59]. For <sup>11</sup>B (I = 3/2), the separation of the satellite transitions  $(\pm 1/2, \pm 3/2)$  defines the quadrupolar frequency  $v_0$  [Eq. (3)]. For crystallographic sites with axial symmetry this equation simplifies as  $\eta = 0$ , and for <sup>11</sup>B (I = 3/2) therefore  $2v_0 = C_0$ . An <sup>11</sup>B NMR spectrum at 295 K yielding a  $C_Q$  of 0.58 MHz was measured as shown in Fig. 3(b). Schwarz et al. [55] calculated <sup>11</sup>B  $C_{\rm Q} = 0.589$  MHz in excellent agreement with this experimental value. The measured values of <sup>11</sup>B  $C_0 = 0.58$  MHz and Knight shift = -434 ppm are in reasonable agreement with values first reported by Silver and Kushida [60] measured using continuous-wave spectroscopy. The main <sup>11</sup>B line shape was reported to vanish below 88 K [61] and a transition to antiferromagnetism deduced. Subsequently Funahashi et al. [62], using neutron diffraction, observed a helical magnetic structure in CrB<sub>2</sub> below 88 K. Bauer et al. [53] confirmed the incommensurate spin order reported by Funahashi et al. [62]. Recent ab initio calculations for two-dimensional CrB<sub>2</sub> have predicted a ferromagnetic half metal with  $T_{\rm C} = 175$  K [63].

# E. CrO<sub>2</sub>

In this ferromagnetic oxide the hyperfine interaction at the Cr site is sufficiently large that the <sup>53</sup>Cr spectrum can be conveniently examined in zero applied field. This interaction is progressively thermally averaged to lower values as the temperature rises from 4.2 K to the Curie temperature  $T_{\rm C} = 395$  K [17,64]. CrO<sub>2</sub> has the tetragonal rutile structure and is ferromagnetic below  $T_{\rm C}$ . Until recently this compound was used as the magnetic coating for high-quality magnetic tapes, and having a convenient Curie temperature relative to room temperature makes it attractive for use in flexible magnetic composite devices [64]. An SEM micrograph of the powder [35] displays a characteristic nanorod microstructure [19,20] with typical rod dimensions: length  $\sim$ 200 to 300 nm, diameter  $\sim$ 30 nm. The powder XRD pattern [35] indicates a well-crystallized material with CrO(OH) (Guyanaite) detected as a minor impurity.

The rutile structure implies one distinguishable Cr site per unit cell, so that there should be only one central line visible in the <sup>53</sup>Cr zero-field NMR spectrum. However, two widely separated narrow lines of approximately equal intensity at frequencies  $v_{low}$  and  $v_{high}$  of 26.5 and 37.2 MHz, respectively, are observed at 4.2 K [16–18,20,21]. A self-doping mechanism has been tentatively suggested for the existence of two distinct Cr sites [17]. A hypothesis that the sites originate from intradomain and domain-wall Cr atoms, respectively, has been considered and experimentally discounted [17]. Recently, it has been hypothesized that the two different Cr sites have different 3*d* orbital occupation numbers [20]. Because CrO<sub>2</sub> is a half metal with a Curie temperature above ambient temperature, it is being investigated for use in spintronic devices [65].

The frequencies  $v_{\text{low}}$  and  $v_{\text{high}}$  for these two lines measured in this work at 77, 195, and 295 K (Table II) were located by systematically searching frequencies below the reported values at 4.2 K. Increasing spin-wave excitation as the temperature rises is presumably responsible for the steadily decreasing  $v_{\text{zf}}(T)$  for the two Cr sites as the temperature rises (Fig. 4). There is a correlation with Bloch ferromagnetic spin-wave theory [9,11] that predicts a  $T^{3/2}$  decrease in

FIG. 4. <sup>53</sup>Cr frequencies  $v_{high}$  (**•**) and  $v_{low}$  (**0**) for CrO<sub>2</sub> plotted as function of  $T^{3/2}$ . With best-fit equation and  $R^2$  value displayed for dotted line fits. Data of Yasuoka *et al.* [15] for <sup>53</sup>CrO<sub>2</sub>  $v_{high}$  (**•**) included for information as described in text. <sup>53</sup>Cr frequency ( $\Delta$ ) for Cr<sub>2</sub>O<sub>3</sub> plotted as a function of  $T^{3/2}$  with best fit displayed.

TABLE II. CrO<sub>2</sub> <sup>53</sup>Cr zero-field NMR line peak frequencies  $v_{high}$  and  $v_{low}$  and linewidths  $\Delta v$  at various temperatures below  $T_{\rm C}$ .

magnetization. Using Bloch theory, the data in Fig. 4 for the two Cr sites predict resonance frequencies at 0 K of 26.407 and 37.068 MHz, indicating hyperfine fields at the nuclei of 12.7 and 17.8 T, respectively. The relationship between the hyperfine parameters, the magnetic moment, and the chromium valence is further discussed in Sec. IV G, as is spin-wave theory.

The <sup>53</sup>Cr NMR linewidths diminish along with decreasing signal-to-noise ratio as the temperature rises towards the Curie temperature (Table II and Fig. 5). Within experimental error, the frequency difference ( $v_{high} - v_{low}$ ) remains essentially constant as the temperature rises from 4.2 K with an average value of 10.55 MHz. Shim *et al.* [17] reported the saturation magnetization (measured using a magnetometer) in CrO<sub>2</sub> from 10 to 380 K indicating a  $T^{3/2}$  decrease in magnetization by 50% up to approximately 375 K, followed by a rapid continuous decrease of the remaining 50% of the magnetization toward zero in the critical region at the Curie temperature of 395 K. Recently, Piskunov *et al.* [21] have measured <sup>53</sup>Cr NMR data from 4.2 to 365 K in high-purity CrO<sub>2</sub>, giving values similar to those reported here.

It may be noted that there is no evidence of a quadrupole interaction in the <sup>53</sup>CrO<sub>2</sub> NMR spectrum in the published or present data. Compare TiO<sub>2</sub> (also rutile structure) where the <sup>49</sup>Ti nuclei see a substantial efg ( $C_Q = 13.9$  MHz,  $\eta = 0.19$ ) [66] and  $\alpha$ -VO<sub>2</sub> (rutile) where the <sup>51</sup>V  $C_Q = 2.77$  MHz and  $\eta = 0.86$ . [67]. It is possible that the broad <sup>53</sup>Cr lines have a second-order quadrupole interaction folded in, which, since this quantity generally decreases with increasing temperature, would explain why the observed linewidths decrease with increasing temperature. Takeda *et al.* [20] reported single-

FIG. 5.  ${}^{53}$ Cr NMR line shapes for CrO<sub>2</sub> at 295, 195, and 77 K. Intensity values are shifted on *y* axis for clarity.

crystal <sup>53</sup>CrO<sub>2</sub> NMR measurements at 4.2 K, in an applied magnetic field of 0.3 T parallel to the *c* axis, giving FWHM for the low and high resonances as 190 and 280 kHz, respectively. A rough estimate of the upper limit for  $C_Q$  can be made from the narrowest linewidth that still obscures the quadrupolar splitting, where assuming  $\eta = 0$  and perturbation theory still holds, a second-order perturbed quadrupolar linewidth  $\Delta$  from Eq. (3) where I = 3/2,  $v_L = 0.723$  MHz at 0.3 T, then using the measured FWHM 190 kHz as  $\Delta$  yields estimates for  $v_Q \approx 0.513$  MHz and  $C_Q \approx 1.03$  MHz. Our estimate of 0.513 MHz for  $v_Q$  is in good agreement with a recent estimate of  $v_Q \approx 0.5$  MHz [21]. It can be noted that a (hypothetical) value of  $\eta = 0.4$  decreases  $C_Q$  by only 2.6%. To the best of our knowledge *ab initio* calculations of the <sup>53</sup>Cr efg in CrO<sub>2</sub> have not been published.

The resonance reported by Yasuoka et al. [15] in 1963 for CrO<sub>2</sub> was detected using a marginal oscillator and a superregenerative oscillator. The resonance, which can be attributed to  $v_{high}$ , was reported for 11 temperatures over a range from 77 to 240 K. These data were added to the data shown in Fig. 4 in order to further refine the fit to spin-wave theory  $T^{3/2}$  and resulted in a best fit, y = -0.0012x + 37.104 ( $R^2 = 0.9866$ ), in excellent agreement with that obtained from frequencies measured using zero-field pulsed NMR. It can be noted that neither a  $T^2$  fit nor a linear T fit to these data was as good as the  $T^{3/2}$  fit [11]. Comparison of the <sup>53</sup>Cr zero applied field NMR frequency,  $v_{high}$ , from the present work, Yasuoka et al. [15] and Piskunov et al. [21], with the saturation magnetization data of Shim *et al.* [17] as functions of temperature for CrO<sub>2</sub>, show agreement with Bloch spin-wave theory to T = 340 K or  $T = 0.86 T_{\rm C}$  [35]. Data from 340 to 365 K (up to 0.9  $T_{\rm C}$ ) indicate a rapid continuous decrease of  $v_{high}$  and  $v_{low}$  toward zero in the critical region near the Curie temperature of 395 K [21], although the values of  $v_{zf}$  are still at the 40–50% level of decrease from 4.2 K when measured at 365 K [35]. It remains to be demonstrated whether the local <sup>53</sup>Cr sublattice magnetization transition at  $T_{\rm C} = 395$  K is first order, i.e., a discontinuous drop to zero of spontaneous magnetization (rather than a smooth transition to the paramagnetic state; i.e., zero magnetization). <sup>53</sup>Cr NMR measurements up to and through  $T_{\rm C}$  (395 K) are suggested for future work.

#### F. $Cr_2O_3$

This antiferromagnetic compound has the corundum  $(Al_2O_3)$  structure with one distinguishable Cr atom per unit cell at a site with axial symmetry so that any detectable second-order line shape should indicate an efg with  $\eta = 0$ . An XRD pattern [35] indicated good crystallinity with no trace of impurity. The antiferromagnetic to paramagnetic

FIG. 6. <sup>53</sup>Cr NMR line shapes for  $Cr_2O_3$  in zero field over range of temperatures. Spectrum at 4.2 K adapted from Takeda *et al.* [19].

transition temperature, Néel temperature,  $T_{\rm N} = 307.9 \pm 0.2$  K, was measured using DSC. The DSC traces were made on two separate samples of the powder, and both measurements [35] indicate a lambda anomaly in specific heat at  $T_{\rm N}$ , characteristic of a second-order phase transition.

Antiferromagnetic ordering was established in  $Cr_2O_3$  by Brockhouse in 1953 [68] and Corliss et al. [69,70]. Previous internal NMR, as discussed in Sec. II, has been reported by Rubinstein et al. [14] using a super-regenerative oscillator detector, with a <sup>53</sup>Cr 95% enriched specimen at temperatures from 1.6 to 16 K. Over this relatively small temperature range the NMR line was detected at a constant frequency of 70.43 MHz, with the signal disappearing into the noise above 16 K. The frequency separation of the satellites (<sup>53</sup>Cr, I = 3/2) gave  $\nu_{\rm O} = 0.525$  MHz and  $C_{\rm O} = 1.05$  MHz using Eq. (3) for  $\eta =$ 0. Takeda et al. [19], using a much later, spectroscopically more sophisticated, method, recently reported a similar value of  $v_0 = 0.54$  MHz. The <sup>53</sup>Cr NMR spectrum of Takeda *et al.* [19] at 4.2 K is reproduced here in Fig. 6; its sharp central line centered at 70.43 MHz with clear  $(\pm 1/2, \pm 3/2)$  satellites measuring  $v_Q = 0.54$  MHz ( $C_Q = 1.08$  MHz) can be compared with the <sup>53</sup>Cr spectra reported in the present work as described below.

In the present work, the <sup>53</sup>Cr zero-field NMR signal was searched for below 70.43 MHz, first at 77 K. This search revealed a surprisingly broad line shape (Fig. 6) centered at 68.5 MHz with width 1.7 MHz, delineated by frequency stepping. A search at 195 K located, again by frequency stepping, a somewhat broader essentially featureless line shape of width 2.0 MHz centered at 56.5 MHz. At 295 K a single line at 45.5 MHz of FWHM = 0.16 MHz was measured. The 295 K measurement was repeated and verified the original result. Spectra taken at increasing positive and negative 50-kHz frequency offsets from this value confirmed a single absorption line at 45.5 MHz. It is unclear what line-broadening mechanism is operating at 77 and 195 K and what is happening to remove this mechanism at 295 K. The specimen was studied over a wide temperature range (10-300 K) using synchrotron radiation powder XRD, and there was no indication of a phase transition. The DSC trace [35] starts upwards from 140 K and there are no transitions other than the Néel temperature at 307.9 K. Karnachev et al. [71] studied the rare-earth orthochromite  $Dy_{0.2}Er_{0.8}CrO_3$  ( $T_N = 141 \text{ K}$ ) over the temperature range 58-91 K using zero applied field NMR and observed line broadening attributed to efg inhomogeneity. We can find no other report of line broadening in  $Cr_2O_3$ and suggest further exploration of the mechanism as potentially fruitful future experimental work and DFT calculation. Figure 4 shows a plot of the central-line frequency for <sup>53</sup>Cr in  $Cr_2O_3$  as a function of  $T^{3/2}$  consistent with spin-wave theory, predicting a resonance frequency at 0 K of 70.985 MHz, indicating a hyperfine field at the nucleus of 34.1 T. A hyperfine magnetic field of approximately 19 T still exists at approximately 10 K below the Néel temperature (Fig. 4). Corliss *et al.* [69,70] showed that greater than 50% of the macroscopic magnetization decrease in Cr2O3 powder (measured using neutron diffraction) occurs in the critical region between 295 K and the Néel temperature [35]. The present work suggests that <sup>53</sup>Cr studies of the magnetic sublattice in  $Cr_2O_3$  over a wide temperature range inclusive of  $T_N$  will be fruitful.

# G. Compilation of <sup>53</sup>Cr solid-state NMR in alloys and compounds

Chromium exhibits seven valence states in its alloys and compounds with the most prevalent being Cr(0) for the metal, metallic alloys, and strong field-ligand complexes, and Cr(III) and Cr(VI) for other compounds. The present work has reported NMR spectra for  $3d^6$  Cr(0) paramagnetic (Cr<sub>2</sub>N) and  $3d^6$  Cr(0) antiferromagnetic (CrB<sub>2</sub>) metals, a  $3d^3$  Cr(III) antiferromagnetic ( $Cr_2O_3$ ) semiconductor, a  $3d^2$  Cr(IV) ferromagnetic half metal (CrO<sub>2</sub>), and  $3d^{\circ}$  Cr(VI) diamagnetic (BaCrO<sub>4</sub>, (NH<sub>4</sub>)<sub>2</sub>CrO<sub>4</sub>) insulators. As discussed, <sup>53</sup>Cr magnetic resonance data can be used to elucidate the bonding environment of Cr in materials. Table III summarizes the calculated integer valence and theoretical spin-only magnetic moments expected for chromium in its compounds as compared to the range of reported low-temperature measured magnetic moments [72-76]. Table IV comprehensively summarizes <sup>53</sup>Cr magnetic resonance data for the compounds reported here within the context of data from the literature on Cr alloys and compounds [77–117]. To the best of our knowledge, past <sup>53</sup>Cr solid-state NMR studies have not been tabulated in one place since 1971 [118]. For the literature surveyed here, which covers 1961 to 2022, 73% of the compounds studied are magnetic compounds, with 27% of those having their critical magnetic ordering temperature ( $T_{\rm C}$  or  $T_{\rm N}$ ) above 300 K. For these studies of magnetic materials, 89% report NMR data at zero applied magnetic field.

#### 1. Zero applied field NMR at low temperatures

This section will first focus on magnetic <sup>53</sup>Cr compounds and their NMR data at zero applied magnetic field. In Table IV, for zero applied field NMR reports, we include the low-temperature resonance position of the central line(s); in reports where domain and wall resonances are distinguished, we have included only the data from domains; in reports where  $T_{\rm C}$  or  $T_{\rm N} > 77$  K and measurements were made at both liquid-helium and liquid-nitrogen temperatures, we have included those data for comparison purposes. For the spinecho technique, only domain signals are observed due to the short relaxation times of the broad resonance signals

The reader should consult the references to ascertain XRD structure, phase purity, annealing state, and other experimental factors.

from walls. Three low-temperature zero-field NMR reports attribute separate resonances to domain and domain-wall sites [3,94,119] for CrI<sub>3</sub>, EuCrO<sub>3</sub>, and CrBr<sub>3</sub>, respectively, with the domain-wall resonances located from 0.89 to 1.42 MHz below the domain resonances. Where possible, low-temperature Cr valence is given and it should be noted that in some compounds (mixed valence or those with a phase transition), valence can change with temperature.

The background to the hyperfine interactions at zero applied magnetic field, where the center-line resonance,  $v_{zf}$  (in units of MHz), is a measure of the hyperfine field at the <sup>53</sup>Cr nucleus, has been introduced in Sec. IV A [Eqs. (4) to (7)] under the approximations noted above. NMR measurements as the temperature approaches 0 K (liquid-helium temperatures) in zero field are necessary to minimize thermal effects on the value of the hyperfine constants derived from the data and for comparison with quantum-chemical calculations of hyperfine interactions. The sublattice magnetization, and the resonance frequency, will decrease as the temperature rises due to thermally excited spin waves. <sup>53</sup>Cr zero applied field and magnetization measurements for CrO<sub>2</sub> and Cr<sub>2</sub>O<sub>3</sub> [35] illustrate the frequency-magnetization relationship, i.e., proportionality of  $v_{zf}(T)$  and M(T), along with the  $T^{3/2}$  relationship for temperatures up to  $\sim 0.8$  ( $T_{\rm C}$  or  $T_{\rm N}$ ) (cf. Fig. 4).

The absolute value of the hyperfine coupling constant |A|depends on the configuration and valence of the Cr ion in the compound, indicates the extent of delocalization of the unpaired electron, and can be calculated ab initio for the  $3d^n 4s^0$  ions [120] or calculated from the measured values of  $v_{\rm rf}(0)$  and M(0) for a given compound [1]. Several authors [120–122] calculated A for the chromium  $3d^n 4s^0$  ions, giving the core polarization hyperfine field per unpaired valence electron, within the Hartree-Fock scheme, as -12.5 T/ $\mu_{\rm B}$ . This value results from the approximation of (i) the magnetic hyperfine 3d exchange interaction transferred at the chromium nucleus (through covalency and overlap) as the Fermi contact interaction and (ii) the magnetic moment as the spin density at the nucleus. Values of A derived from low-temperature experiment are compared with theory to ascertain the extent of delocalization or magnitude of the transferred field. Alternatively, theoretical values of A are used with measured values of  $v_{zf}$  at low temperature to predict magnetization and valence. The ground-state magnetization can also be calculated using ab initio DFT methods, where the approximation of the exchange and correlation potential is the subject of much research in chromium compounds [123–126].

Other methods for the calculation of the hyperfine coupling constant have been reported for <sup>53</sup>Cr with values of |A| ranging from 8.3 to 12.2 T/ $\mu_B$  [126–130]. The value A = -10T/ $\mu_B$  is often used, as this is the average value for the core polarization hyperfine field per unpaired valence electron for the 3*d* transition metals reported by Blugel *et al.* [129]. The value of |A| = 8.33 T/ $\mu_B$  results from a first-principles calculation of the contact field for Cr<sup>3+</sup> [126]. Rubinstein *et al.* [14] first reported the measured value of A = -9.76 T/ $\mu_B$  based on zero applied field measurements of <sup>53</sup>Cr<sup>3+</sup> in an octahedral environment of oxygen atoms in Cr<sub>2</sub>O<sub>3</sub> with  $v_{zf} = 70.43$  MHz at 1.6 K and with *M*(0) assumed to be  $3\mu_B$  per Cr atom. The theoretical value of |A| for an isolated Cr<sup>3+</sup> ion (12.5 T/ $\mu_B$ ) has been shown to be very close to the measured values (11.3

FIG. 7. (a) Magnetic moment as function of valence for Cr compounds, and (b)  $^{53}$ Cr zero applied field magnetic resonance frequency near 0 K as function of Cr valence.

to 12.4 T/ $\mu_B$ ) in Cr molecular rings and chains [10,104,105]. The theoretical values compare favorably with the range of measured (calculated from measurements on Cr compounds) values of |A| shown in Table III.

Table III is also useful for estimating the range of observed frequencies near 0 K for the <sup>53</sup>Cr nucleus in various compounds. Using the range of |A| values and the spin-only magnetic moment values, the anticipated range of  ${}^{53}$ Cr  $\nu_{zf}(0)$ is 38–110 MHz; using the measured local magnetic moment values, the anticipated range is 10-114 MHz, as compared to the reported measured range of  $v_{zf}$  in Table IV which is 13–82 MHz. This measured range of  $v_{zf}(0)$  reported for each configuration in Table IV can be compared to the range calculated from Table III in a form of Slater-Pauling-like curve [see Fig. 7(a) and Fig. 7(b)]. The Slater-Pauling curve (magnetic moment M as a function of valence electron concentration) for 3d transition-metal compounds has been calculated ab initio by Dederlichs *et al.* [130] for Fe-, Ni-, and Co-based alloys. Such an ab initio calculation for Cr-based alloys has not been reported and is recommended as fruitful future work.

The theoretical value  $|A| = 8.33 \text{ T}/\mu_{\text{B}}$  [126], along with the spin-only magnetic moment values from Table III for each valence, are used to calculate the theoretical internal-field frequencies for each valence in Fig. 7(b). Figure 7(b) shows that the value of the hyperfine interaction constant |A| has a great bearing on the goodness of fit between theory and experiment. It can be noted that a variation in |A| from 8.3 to 12.5 T/ $\mu_{\text{B}}$ results in a variation of predicted resonance frequency [e.g., for Cr(III), using spin-only  $M = 3 \mu_{\text{B}}$ ] from 60 to 90 MHz. In addition, it should be noted that in Fig. 7(b) the mixedvalence compounds are shown together at the boundaries of the integer valence values, which may also affect goodness of fit.

Future work on *ab initio* calculations for magnetic Cr alloys and compounds would be useful and could help predict the mixed-valence values for  $v_{zf}(0)$ . Mixed valence is thought to enable local double-exchange mediated magnetic order [131] which, in topological insulators, is postulated as a pathway to room-temperature quantum transport in zero magnetic field [132,133]. Also, *ab initio* calculations of  $v_{zf}(0)$  would be helpful for locating Cr(I) and Cr(V) internal-field resonances that, to the best of our knowledge, have not yet been reported by zero-field NMR studies. In Fig. 7(b) we have indicated, with dashed-line ellipses, where one might expect to find the low-temperature <sup>53</sup>Cr zero applied field NMR resonances for  $3d^5$  low spin and  $3d^1$  compounds in future experiments or calculations.

Some further comments on Fig. 7(b) are warranted as it is the first time the literature data for <sup>53</sup>Cr have been compiled in such a format. As reviewed in this section, previous <sup>53</sup>Cr reports have mainly focused on a single material with a single Cr valence (predominantly  $Cr^{3+}$ ), with authors choosing either to fix the hyperfine coupling constant A or to fix the magnetic moment. The data in Fig. 7(b) now provide a summary of  $^{53}$ Cr  $v_{zf}(0)$  values for a wide range of Cr compounds across the valences Cr(0) to Cr(IV) including mixed valence, high spin, low spin, octahedral and tetrahedral configurations, metals, half metals, semiconductors, insulators, and varying crystal and magnetic structures. These data allow us to test our understanding of magnetism in Cr alloys and compounds. Cottenier [134] noted the difficulty of DFT functionals in capturing the physics of the ground state for Cr alloys and compounds, making these alloys ideal testing grounds for improved DFT functionals. The dataset may also prove helpful as a training set for a machine-learning approach to property prediction as well as testing hypotheses and models.

(1) It can be found in the literature that the covalency of the Cr – x bond increases as x = O is successively replaced by x = halides, x = S, and x = Se [121]. The "covalency school model" [121] expects the magnetic moment of the electron spins (and hence  $v_{zf}$ ) to decrease with decreasing electronegativity, i.e., with increasing covalency, which it does as shown in Fig. 7(b) for  $d^3$  Cr(III)<sup>oct</sup> oxides, halides, sulfides, and selenides.

(2) The reported noninteger valence values for mixedvalence compounds from Table IV have been plotted as an expanded section [35] and show the expected decrease in lowtemperature <sup>53</sup>Cr internal magnetic field resonance frequency with valence from  $Cr^{3+}$  to  $Cr^{4+}$  for mixed-valence chromium oxides. (3) The two Cr<sup>2+</sup> high-spin  $d^4$  Cr(II)<sup>oct</sup> compounds may appear as outliers; however, they are high spin and sit approximately where they would be predicted using the spin-only magnetic moment M = 4 and |A| = 8.33 T/ $\mu_B$ .

Hence, the internal-field data near 0 K can be used to gain knowledge of the local internal field at the <sup>53</sup>Cr nucleus in the ground state and can be used to understand the valence state. As discussed in the next section, the temperature dependence of the magnetic resonance central frequency for systems adequately modeled by spin-wave theory can also prove useful for understanding magnetic stability.

#### 2. Zero applied field NMR as a function of temperature

As discussed in Sec. IV E, the internal-field data as a function of temperature well below the critical temperature region (<0.8  $T_{crit}$ ) may be modeled using the Bloch  $T^{3/2}$  relation which is valid for any crystal structure [135]. Table V provides data for Cr compounds (in addition to CrO<sub>2</sub> and Cr<sub>2</sub>O<sub>3</sub>) where the magnetization (antiferromagnetic, ferromagnetic, and ferrimagnetic) can be modeled to a first approximation by Bloch spin-wave theory. The magnetic resonance data for these 16 compounds are summarized in Fig. 8.

Bastow *et al.* [137,138] showed that experimental Debye-Waller factors for a range of crystalline solids also have a  $T^{3/2}$  dependency attributed to the variation of the mean-square amplitude of vibration of atoms in crystals over a temperature range from the Debye temperature to close to the melting point. As the data in Fig. 8 are for crystalline compounds far below their Debye temperature, the  $T^{3/2}$  dependency can be attributed to the fundamental magnetization behavior described by spin-wave theory [11]. The goodness-of-fit values for these data (Table V [35]) support further investigation of parameters that can be extracted from the Bloch spin-wave relationship for the temperature dependence of the magnetization *M* at  $T < T_{crit}$  as follows [11,135]:

$$M(T)/M(0) = 1 - a_{3/2}(T)^{3/2},$$
 (8)

where  $a_{3/2}$  has units of  $K^{-3/2}$  and is related to the spin stiffness in zero field, *D*, using the relationship [135]

$$a_{3/2} = [2.612(g\mu_{\rm B})/(\rho M(0))][k_B/(4\pi D)]^{3/2}, \qquad (9)$$

where g is the dimensionless Landé g factor,  $\rho$  is the density in kg/m<sup>3</sup>,  $\mu_{\rm B} = 9.27 \times 10^{-24}$  J/T,  $k_B = 8.617 \times 10^{-5}$  eV/K, and M(0) is the saturation magnetization at 0 K in J/(T kg). Rewriting Eq. (8) using the relationship between  $v_{\rm zf}$  and M in Eq. (7) and as presented in Table V gives

$$v_{\rm zf}(T) = v_{\rm zf}(0) - c(T/T_{\rm crit})^{3/2}$$
(10)

where  $v_{zf}(0)$  is related to the electronic and magnetic properties, and the slope,  $c = a_{3/2} v_{zf}(0)(T_{crit})^{3/2}$  with the parameter  $a_{3/2}$  related to the lattice geometry and magnetic exchange interaction. Since the data are well fitted to the Bloch  $T^{3/2}$  relationship, the spin-wave excitation gap can be considered negligible [139]. For the 16 compounds in Table V, values of  $a_{3/2}$ , density, and low-temperature saturation magnetization are given in Ref. [35] and used to calculate spin stiffness *D*. Figure 9(a) shows that the low-temperature saturation magnetization values reported in the literature for these Cr compounds as compared to values calculated from  $v_{zf}(0)$

FIG. 8. Bloch spin-wave theory applied to internal-field NMR center-line frequency,  $v_{zf}$ , data for 16 compounds using data adapted from literature cited in Table V.

are in very good agreement, in support of the validity of Eq. (7) for these compounds. As shown in Table V, the compound with the highest slope *c*, CrCl<sub>3</sub>, has the lowest spin stiffness of 4.7 meV Å<sup>2</sup>. The compound with the lowest slope *c*, Cr<sub>3</sub>AsN, has the highest spin stiffness of 410 meV Å<sup>2</sup>. Only 2 of the 16 compounds have published values for *D* from magnetic measurements or theory, and these are CrI<sub>3</sub>,  $D = 27 \pm 6 \text{ meV } Å^2$  [139], where the error bars of ~20% reflect the population standard deviation for different samples, and CrO<sub>2</sub>,  $D = 91 \text{ meV } Å^2$  [140]. Both published *D* values for these ferromagnetic compounds compare well (within ~15%) with the values calculated from the internal-field data as shown in Table V. Calculation of *D* from magnetization data for the antiferromagnetic semiconductor ZnCr<sub>2</sub>Se<sub>4</sub> [141] gives  $D = 13.7 \text{ meV } Å^2$  within 3%

of the value  $D = 14.1 \text{ meV } \text{Å}^2$  calculated from the internalfield data. Calculation of D from magnetization data for the antiferromagnetic semiconductor  $\text{Cr}_2\text{O}_3$  [69] gives D = $61.2 \text{ meV } \text{Å}^2$  within 20% of the value  $D = 76.3 \text{ meV } \text{Å}^2$  calculated from the internal-field data. The D value calculated for  $\text{Cr}_3\text{AsN}$  can be compared with D values for other metals. Lowde [142] published D values for the metallic CrFe system in the range  $100 - 300 \text{ meV } \text{Å}^2$ , and Lewis [143] reported  $D = 284 \pm 40 \text{ meV } \text{Å}^2$  for metallic ferrimagnetic Pt<sub>3</sub>Cr; all values are the same order of magnitude as the value calculated for metallic ferrimagnetic  $\text{Cr}_3\text{AsN}$  in Table V, noting that an analysis of published magnetic measurements of  $\text{Cr}_3\text{AsN}$ [78] suggests  $D = 229 \text{ meV } \text{Å}^2$  which is ~40% lower than the value from internal-field magnetic resonance data. Thus, the values of D in Table V appear reasonable for ferro-, ferri-, and

FIG. 9. (a) Comparison of spontaneous magnetization at low temperature as reported from magnetic measurements and as calculated from internal-field magnetic resonance data. (b) Spin stiffness and critical temperature for the  $d^3$  Cr(III)<sup>oct</sup> compounds in Table V, including ferromagnetic, antiferromagnetic, and ferrimagnetic compounds.

<sup>53</sup>Cr Knight Shift or Chemical Shift (ppm)

FIG. 10. Knight shift or chemical shift for  ${}^{53}$ Cr compounds from Table IV. Shift is with respect to saturated aqueous solution of alkali chromate [Na<sub>2</sub>CrO<sub>4</sub> or (NH<sub>4</sub>)<sub>2</sub>CrO<sub>4</sub>].

antiferromagnetic chromium compounds, and this tabulation can be useful for comparison with magnetic measurements or density-functional approaches to the calculation of spin stiffness in Cr alloys and compounds. Figure 9(b) shows the relationship between spin stiffness and critical transition temperature for the Cr(III)  $d^{3oct}$  subset of compounds from Table V. This relationship  $D = (0.45 \text{ meV } \text{Å}^2/\text{K})T_{crit}$  resembles that reported for a family of magnetic cobalt Heusler alloys of  $D = (0.36 \text{ meV } \text{Å}^2/\text{K})T_{crit}$  [144]. The relationship between spin stiffness D and  $T_{crit}$ , for all Cr alloys and compounds from Table V, is  $D = (0.37 \text{ meV } \text{Å}^2/\text{K})T_{crit}$  [35].

#### 3. External-field NMR

The second focus of Sec. IV G is inclusive of nonmagnetic Cr compounds. Two recent solid-state NMR reviews commented on the challenges of recording <sup>53</sup>Cr solid-state NMR spectra, citing only three reports on <sup>53</sup>Cr NMR of the diamagnetic octahedral  $Cr(0) d^6$  compound  $Cr(CO)_6$  and diamagnetic tetrahedral  $Cr(VI) d^0$  chromates and dichromates [23,24]. The comprehensive up-to-date summary of magnetic and nonmagnetic compounds presented in Table IV permits an expanded discussion of the <sup>53</sup>Cr solid-state NMR characteristics of interest to experimentalists and theorists. The range of  $C_0$  observed for these compounds [Cr(0), Cr(II), Cr(III), Cr(IV), mixed valence, and Cr(VI)] is 0.2 MHz  $\leq C_Q \leq 8.28$ MHz. The range reported in diamagnetic alkali-earth chromate and dichromate compounds alone is 1.28 MHz  $\leq C_0 \leq$ 8.28 MHz [22,44], all with Cr(VI) electron configuration. Some generalizations can be made based on the data in Table IV—the Cr compounds with  $C_Q \leq \sim 1$  MHz tend to be semiconductors. Insulating compounds have Co values ranging from 1.3 to 4.4 MHz. The compounds with  $C_0 > 4$  MHz tend to be semiconductors and metals. These observations provide some general guidelines for the likely magnitude of  $C_{\rm O}$  to be found in such materials. These are some of the parameters that could feature in an NMR crystallography approach to detailed local structural characterization.

As discussed in Sec. IV A, DFT calculations of Knight shifts and chemical shifts in transition-metal compounds require orbital and spin contributions to accurately reproduce the experimental values. Knight shifts for the <sup>53</sup>Cr compounds in Table IV range from –9982 to 6990 ppm and can be temperature dependent. As shifts are reported relative to the

Cr ion in solution, ionic compounds typically have shifts near 0 ppm, i.e., -100 ppm  $<\delta < 100$  ppm (see Fig. 10). As (CO)<sub>6</sub> is a strong field ligand, the Cr(0) complex Cr(CO)<sub>6</sub> is more shielded (-1814 ppm) than the chromate salts. As bonding covalency increases, leading finally to metallic conduction, the shielding also increases and the Fermi contact term dominates the contribution to the shift. As shown in Table IV, the present work, to the best of our knowledge, has measured the largest Cr(0) Knight shift (-9982 ppm for CrB<sub>2</sub>) for any chromium-containing metallic material reported to date. Figure 10 illustrates the range of chemical and Knight shifts for <sup>53</sup>Cr alloys and compounds.

The hyperfine coupling constant A, or the core polarization hyperfine field per unpaired valence electron for the 3dtransition-metal <sup>53</sup>Cr, plays a role in the shielding of the nucleus or the magnetic shift away from the Larmor frequency that can be measured by NMR. The exchange polarization between d electrons on the Fermi surface and s electrons in the core orbitals dominates the Knight shift and leads to the large observed Knight shifts in metallic Cr compounds shown in Fig. 10 [31]. In Sec. IV G1 we have shown that the value of |A| of 8.33 T/ $\mu_B$  reasonably describes Cr alloys across the range of crystal structures. Assuming A is independent of temperature, the Knight shift should be proportional to the magnetic susceptibility, such that a large Knight shift is indicative of a large Pauli spin susceptibility  $\chi_{\rm P}$  per Cr atom [Eq. (4)]. The experimental magnetic susceptibility of CrB<sub>2</sub> at room temperature in the paramagnetic state has been reported in a range from 0.485 to 0.795  $(10^{-3} \text{ cm}^3/\text{mol})$ [145–148]. Using this range for susceptibility and the measured <sup>53</sup>Cr Knight-shift value of -0.9982% reported here, the Clogston-Jaccarino [149] analysis can be applied [35], assuming negligible orbital contribution to the Knight shift and negligible transferred hyperfine field, resulting in a range of values for |A| from 7.0 to 11.5 T/ $\mu_B$ , in agreement with the treatment presented in Sec. IV G 1. Ab initio calculation of the magnetic susceptibility for CrB2 metal in the paramagnetic state suggests that the magnetic susceptibility is dominated by the spin contribution,  $\chi_{spin} = 0.703 \ (10^{-3} \text{ cm}^3/\text{mol})$ , in agreement with experimental results [146]. It can be noted that Laskowski and Blaha [37] have calculated the Knight shift and magnetic susceptibility for Cr metal including orbital and spin contributions, with their theoretical values coming within 10% of the measured values. Our results suggest that theoretical calculation of the Knight shift for  $CrB_2$  should be the subject of fruitful future work.

# 4. Hyperfine interactions as a guide to the production of novel materials

A theme of the discussion thus far has been the ability of magnetic resonance to determine parameters that can be useful to check theoretical models and their predictions in magnetic and nonmagnetic Cr alloys and compounds. In addition, it is suggested that the hyperfine interactions probed by magnetic resonance are useful guides for the selection and production of novel materials for industrial applications. The multivalent nature of chromium makes for a variety of stable compounds with diverse magnetic properties. The ability to tune and control room-temperature accessible magnetic states makes chromium alloys and compounds prime candidates for quantum engineering devices, and NMR adds to the ways these states can be probed. The results presented here have shown a correlation between the critical transition temperature ( $T_{\rm C}$  or  $T_{\rm N}$ ) and the spin stiffness in zero field, D, calculated from magnetic resonance data for Cr alloys and compounds. The local, site-specific nature of magnetic resonance as a probe technique means that this approach can be used across a range of valences, including mixed valence, various crystal structures, and ferro-, ferri-, and antiferromagnetic order. D is a measure of the resistance of the spin lattice to thermal disturbance; hence, the magnetic resonance parameters enable an indirect test of the robustness of spin polarization in Cr alloys and compounds. The data presented here can also guide the discovery of technologically important ferro-, ferri-, and antiferromagnetic materials with high critical temperatures and stable properties given the correlations that have been developed here. A number of approximations are involved in the treatment of these compounds using Bloch spin-wave theory including (i) dominance of spin rather than spin-orbital contributions, (ii) same treatment for all crystal and magnetic structures, (iii) temperature-independent and valence-independent hyperfine coupling constant, (iv) an isotropic Fermi contact interaction, and (v) dominant core polarization contribution to the hyperfine field, such that the treatment points to some key features as drivers of behavior in these systems. With the accumulation of experimental data for training sets, it is hoped that these key features will be able to be investigated using machine learning. Extending this approach, one might speculate what local site properties at chromium could be related directly to the macroscopic properties needed, such as the size of the efg as a characteristic of the local site distortion and the impact on quantum switching. In low-dimensional spin systems, hyperfine fields contribute to decoherence in the system, leading to limitation in the performance of potential quantum devices [126].

#### V. SUMMARY

This study encompassing new experimental observations and a comprehensive survey of magnetic resonance parameters collected on <sup>53</sup>Cr shows it can be quite a receptive nucleus for NMR with an external field or zero field. Therefore <sup>53</sup>Cr NMR can be used to characterize a range of important materials including metals, half metals, insulators, semiconductors, ferromagnetic, antiferromagnetic, and diamagnetic materials. The <sup>53</sup>Cr solid-state NMR work to date of relevance to the new observations here has been summarized and put into context. The work presented here has established quadrupolar coupling constants and chemical/Knight shifts for the first time for several important compounds. The  $T^{3/2}$  behavior of the sublattice magnetization of CrO<sub>2</sub> and Cr<sub>2</sub>O<sub>3</sub> measured via <sup>53</sup>Cr zero applied field NMR are reported here over a wide temperature range from liquid He temperature to room temperature. The large negative Knight shift of <sup>53</sup>Cr in the transition-metal intermetallic CrB<sub>2</sub> has been measured. Unexplained line shapes have been reported here for high-purity  $Cr_2O_3$ , and these should be the subject of future verification and elucidation. Also, as in the case of AlN, it may take careful single-crystal work or enriched specimens or both to pinpoint singularities and  $C_{\rm O}$  values in some of the Cr compounds discussed here, where only an upper limit on  $C_Q$  could be estimated.

The first comprehensive summary of <sup>53</sup>Cr NMR interaction parameters for chromium compounds reported from 1961 to 2022 has been tabulated. Here is shown how low-temperature internal-field central frequencies have been correlated with valence state, and spin stiffness has been calculated for 16 chromium compounds. The local information provided from <sup>53</sup>Cr NMR complements bulk measurements. Therefore, such NMR data can help determine whether new materials show promising characteristics, and, if one could go further and relate these characteristics directly to site parameters (e.g., shift, anisotropy, efg), then one could have a direct measure of desirable properties. Additional theoretical and computational studies have been suggested based on current gaps in the data for <sup>53</sup>Cr NMR parameters. Knowledge of these parameters will enable further progress in understanding and capturing the benefits from electronic and magnetic structure-propertyfunction relationships in Cr compounds.

*Note added*. While this manuscript was in preparation, one of the authors, Timothy J. Bastow, passed away.

#### ACKNOWLEDGMENTS

We gratefully acknowledge CSIRO: Aaron Seeber for the XRD scans, Mark Greaves for the SEM, Yesim Gozukara for the DSC, and ANSTO: Justin Kimpton for the research undertaken on the powder-diffraction beamline at the Australian Synchrotron, part of ANSTO. M.E.S. thanks both the University of Southampton and EPSRC for supporting his research. Professor Ekaterina Izgorodina is thanked for helpful discussions. Adrian Trinchi and Lyndsey Benson are thanked for their support of the work as the leaders of the Functional Powders team at CSIRO. A.J.H., K.M.N., and M.E.S. are grateful to Timothy J. Bastow, now deceased, for sharing his fascination with chromium and passion for magnetic resonance with them.

T.J.B. devised the experimental plan, contributed the overall supervision of this work, performed NMR measurements, data analysis, and cowrote the manuscript. A.J.H. assisted in data collection and analysis and cowrote the manuscript. K.M.N. and M.E.S. assisted in data analysis and editing of the manuscript.
