(Received 4 May 2021; accepted 30 July 2021; published 17 September 2021)

We report on the observation and coherent excitation of atoms on the narrow inner-shell orbital transition, connecting the erbium ground state $[\text{Xe}]4f^{12}(^3\text{H}_6)6s^2$ to the excited state $[\text{Xe}]4f^{11}((^4\text{I}_{5/2})^0)5d(^5\text{D}_{3/2})6s^2(^{15/2}, ^{3/2})_7^0$. This transition corresponds to a wavelength of 1299 nm and is optically closed. We perform high-resolution spectroscopy to extract the g_J factor of the 1299-nm state and to determine the frequency shift for four bosonic isotopes. We further demonstrate coherent control of the atomic state and extract a lifetime of 178(19) ms, which corresponds to a linewidth of 0.9(1) Hz. The experimental findings are in good agreement with our semi-empirical model. In addition, we present theoretical calculations of the atomic polarizability, revealing several different magic-wavelength conditions. Finally, we make use of the vectorial polarizability and confirm a possible magic wavelength at 532 nm.

I. INTRODUCTION

Ultranarrow atomic transitions are an extremely powerful resource for high-precision measurements and for controlling and manipulating atoms on a quantum level [1]. Prominent examples are clock transitions in alkaline-earth-like atoms [2–4]. The small spectral linewidth of these transitions enables the high-resolution detection of energy shifts on very fine scales. This unique property made it possible, e.g., to observe SU(N)-symmetric interactions in both, ytterbium and strontium [5,6]. An additional important avenue paved by narrow transitions is the optical manipulation and coherent control of ultracold atoms. The tuning of the interparticle interactions using optical Feshbach resonances has been demonstrated and benefits from the narrow linewidth due to the suppressed photon scattering rate [7–11]. Coherent control enabled the creation of ultracold molecules via Raman state transfer [12–15], the preparation of the atoms in different nuclear spin configurations [5,6], and the creation of spin-orbit coupled quantum gases [16–19]. Finally, the coherent

excitation allows for the realization of quantum computation and quantum simulations, e.g., with neutral atoms loaded into optical lattices [20–22].

Atomic species of the lanthanide family are multivalence electron atoms and possess a special electron configuration, a so-called submerged shell, in which the 6s subshell is filled, while the lower-lying 4f or 5d subshells are open, being partially unoccupied. This leads to a large variety of optical transitions in these elements, whose linewidths range from tens of μHz to tens of MHz [23–25]. In contrast to alkaline-earth-like atoms, which do not carry a magnetic moment in their ground state, a selection of lanthanides allow for the combination of a narrow transition with a large magnetic moment. While narrow and ultranarrow transitions have been extensively studied in alkaline-earth and ytterbium atoms, only little is known for the other elements of the lanthanide series. Some spectroscopic studies have been carried out for dysprosium [26] and thulium [27,28].

For the specific case of erbium, there is a prediction of a narrow inner-shell orbital transition, which has a change in the total angular momentum of $\Delta J = +1$ ($|J = 6\rangle \rightarrow |J' = 7\rangle$) and a change in the total spin of $\Delta S = 1$ [23]. The transition involves the excitation of a 4f ground-state electron to a 5d state; see Fig. 1. Theoretical calculations predict a linewidth of about 2 Hz [23], which fills a gap between ultranarrow transitions in the mHz regime and transitions having linewidths on the order of kHz, available in alkaline-earth atoms and previously explored in lanthanide atoms. Moreover, in contrast to most narrow transitions in other atomic species, the wavelength of 1299 nm lies within the telecom-wavelength window, which, e.g., is advantageous for the application in quantum communication systems [29–32]. Here, we report on the experimental observation of this transition. We perform a

Schematic level scheme illustrating the $[\text{Xe}]4f^{12}({}^3\text{H}_6)6s^2 \rightarrow [\text{Xe}]4f^{11}({}^4\text{I}_{15/2})^0 5d({}^5\text{D}_{3/2})6s^2({}^{15/2}, {}^{3/2})_7^0$ inner-shell orbital transition at 1299 nm ($|g\rangle \rightarrow |e\rangle$) and the $[\text{Xe}]4f^{12}({}^3\text{H}_6)6s^2 \rightarrow [\text{Xe}]4f^{12}({}^3\text{H}_6)6s6p({}^1\text{P}_1)^0(6, 1)_7^0$ transition at 401 nm, used for absorption imaging. The horizontal lines indicate the energy levels for $|g\rangle$ (blue, even parity), $|e\rangle$ (red, odd parity), and the state at 401 nm (black, odd parity). $[\text{Xe}]$ stands for the electron configuration of xenon. The insets illustrate the electron configurations. The grey shaded boxes represent the Zeeman manifold for $|g\rangle$ and $|e\rangle$. Energies are not to scale.

careful experimental survey and characterization of the 1299-nm transition, realizing the first crucial step towards extended applications, e.g., to explore novel few and many-body phenomena in dipolar or large spin systems.

We experimentally observe the transition at 1299 nm for the bosonic isotopes ^{164}Er , ^{166}Er , ^{168}Er , and ^{170}Er and for the fermionic isotope ^{167}Er . We perform high-resolution spectroscopy to determine the g_J factor of the excited atomic state ($|e\rangle$) and to measure the frequency shift for the four bosonic isotopes. We further demonstrate coherent control of the atomic state and measure an excited-state lifetime of 178(19) ms. We carry out trap frequency measurements to determine the atomic polarizability of the excited state relative to the ground state with the trapping light at 532.2 nm. As we vary the polarization of the light we take advantage of the vectorial term of the atomic polarizability and we are able to get close to a magic-wavelength condition, where the ground state ($|g\rangle$) and $|e\rangle$ feature the same polarizability. We finally present theoretical calculations of the atomic polarizability based on a sum-over-states formula and report on several alternative options for magic wavelengths.

II. EXPERIMENTAL SETUP

We search for the narrow inner-shell transition by performing spectroscopic measurements on a trapped quantum-degenerate erbium gas. Our experimental procedure to create an erbium Bose-Einstein condensate (BEC) follows Ref. [33]. In brief, after laser cooling in a magneto-optical trap, we load the atoms into a crossed optical dipole trap (ODT) operating at 1064 nm and perform evaporative cooling down to quantum

degeneracy. The BEC typically contains $N = 1\text{--}3 \times 10^4$ atoms with BEC fractions ranging from 30–80%, depending on the isotope choice. For the fermionic ^{167}Er isotope, we obtain a degenerate quantum gas of $N = 2 \times 10^4$ atoms at a temperature of $T \approx 0.5T_F$, where T_F is the Fermi temperature. During the evaporation, a homogeneous magnetic field B is applied to ensure that the atomic cloud remains spin-polarized in the lowest Zeeman level $m_J = -6$ ($m_F = -19/2$) for the bosonic (fermionic) isotopes.

The light for driving the narrow inner-shell transition is generated from an external-cavity diode laser (ECDL) operating at 1299 nm. We determine the absolute frequency of the laser by measuring the frequency-doubled light with a calibrated wavemeter [34], which has an accuracy of 60 MHz. For our coarse spectroscopy, we use the wide tunability of the ECDL via the control of a piezoelectric element, which allows us to change the laser frequency. Furthermore, we can narrow the laser linewidth and stabilize the frequency using a high-finesse reference cavity made of ultralow expansion glass. The reference cavity has a free spectral range (FSR) of 1.4972462(3) GHz and finesse of about 175000. The stabilized laser system has an Allan deviation of 3.1×10^{-15} over an observation time of 1 s. The coherence time is extracted from the phase noise power spectral density and corresponds to 96 ms [35]. We measure a linear frequency drift of the high-finesse cavity of 4.34(7) kHz/day. In the experiment, we use the frequency stabilized configuration for the high-resolution spectroscopy.

III. COARSE SPECTROSCOPY

In the 1960s, the atomic spectra of lanthanides began to attract interest. Absorption lines were observed using King's furnace or oxyacetylene flames in the range between 650 to 250 nm [36,37]. In early spectroscopic works, the configuration of the low-lying energy levels, and particularly that of the odd parity states, was not known. The first work to identify the odd-parity level $4f^{11}5d6s^2$ —i.e., ortho-erbium ground state—as the lowest-lying configuration above $|g\rangle$ was Ref. [38]. In this configuration, the angular momentum $J_1 = 7/2$ of the $4f^{11}$ core couples via $J_1 - j$ coupling to the j of the $5d$ electron, which leads to a total of 10 fine structure levels with J ranging from 5 to 10. The assignment of the fine structure levels has been deduced by analyzing energy differences between absorption lines using a spectroscopic-level searching algorithm. The NIST database reports the energies of the corresponding fine-structure levels, referring to unpublished measurements from mid 70 s [39]. For our level of interest $|e\rangle = 4f^{11}({}^4\text{I}_{15/2})^0 5d({}^5\text{D}_{3/2})6s^2({}^{15/2}, {}^{3/2})_7^0$, the wavenumber given by NIST [40], not accounting for the isotope shift, is

$$\bar{\nu}_{\text{NIST}} = 7696.956 \text{ cm}^{-1}. \quad (1)$$

To the best of our knowledge, prior to this paper, there has been no direct measurement of the 1299-nm transition. Our ultracold quantum gas provides a new opportunity to observe and characterize this transition.

We start our search of the line by performing a coarse spectroscopy over a broad frequency range around $\bar{\nu}_{\text{NIST}}$ (corresponding to $\nu_{\text{NIST}} = 230.738 \text{ THz}$). After preparing an

FIG. 2. Coarse spectroscopy results for the four bosonic isotopes ^{164}Er , ^{166}Er , ^{168}Er , and ^{170}Er at $B = 1.355(5)$ G and for the fermionic isotope ^{167}Er at $B = 0.52(5)$ G. The normalized atom number in $|g\rangle$ is plotted versus the laser frequency, which is controlled by the piezoelectric element of the ECDL. The atom number is normalized to the moving median formed by 21 data points.

optically-trapped ultracold erbium gas in $|g\rangle$, we shine the 1299-nm spectroscopy light on the sample. The spectroscopy beam has a peak intensity of $I_{\text{peak}} \approx 0.8 \text{ W/cm}^2$ and a $1/e^2$ waist of about $110 \mu\text{m}$. The irradiation time is 100 ms, during which we sweep the laser frequency with an amplitude of about ± 40 MHz. After irradiation, we release the atoms from the trap for a free expansion of 30 ms. We record the number of remaining $|g\rangle$ atoms by performing standard absorption imaging using resonant light at 401 nm (see Fig. 1).

We record the absorption spectrum by repeating the measurement over a wide frequency range with a step size of 40 MHz. Figure 2 summarizes our results for the four most abundant bosonic erbium isotopes (^{164}Er , ^{166}Er , ^{168}Er , and ^{170}Er) and for the fermionic ^{167}Er isotope. As expected from their zero nuclear spin ($I = 0$), each bosonic isotope exhibit just one resonant absorption line, detected as a sharp dip in the number of $|g\rangle$ atoms when varying the 1299-nm laser frequency. For the fermionic ^{167}Er isotope, possessing a hyperfine structure ($I = 7/2$), we identify three resonances. We attribute the three resonances to the transitions $|F = 19/2\rangle \rightarrow |F' = 21/2\rangle$, $|F = 19/2\rangle \rightarrow |F' = 19/2\rangle$, and $|F = 19/2\rangle \rightarrow |F' = 17/2\rangle$, respectively. Notably, at the resonance positions, the population of $|g\rangle$ reaches values below 0.5, indicating an underlying loss mechanism, such as heating from a reduced trapping potential for $|e\rangle$ or an interaction-based loss processes.

IV. HIGH-RESOLUTION SPECTROSCOPY

Thanks to the coarse spectroscopy measurements, we can now restrict the frequency region of interest and perform a spectroscopy survey with a much higher spectral resolution and lower laser intensity, allowing also to resolve the magnetic Zeeman sublevels.

For this, we stabilize the laser frequency to the high-finesse reference cavity and then precisely tune the laser frequency using an acousto-optical modulator. The recorded absorption spectra have a step size ranging from 1 to 8 kHz, depending on the measurement. Moreover, the spectroscopy is now performed with a free-falling gas to eliminate possible ac Stark shifts, eventually caused by the ODT light at 1064 nm. Therefore, after sample preparation, we switch off all trapping lights, and then irradiate the sample with a 1299 nm spectroscopy pulse of 1 ms, corresponding to a Fourier limited linewidth of 800 Hz. The pulse has a peak intensity of $I_{\text{peak}} \approx 25 \text{ mW/cm}^2$. To minimize the possible frequency shifts caused by the Doppler effect in a free-falling sample, the 1299-nm laser beam propagates in a plane orthogonal to the vertical direction, defined by gravity. The quantization axis, defined by our bias magnetic field, is oriented along the vertical direction. The light contains contributions from all light polarizations, such that the 1299-nm beam can induce σ^+ , σ^- , and π transitions; see inset in Fig. 3(a).

Figure 3(a) shows the ground-state population for the ^{168}Er isotope as a function of the laser detuning, plotted with respect to the central frequency of the π transition. We clearly observe three resonant dips in the ground-state population, corresponding to the transitions from the ground-state level $m_J = -6$ to the excited Zeeman sublevels $m_J = -7$, -6 and -5 . We extract the center frequency and the transition linewidth by fitting the spectroscopy signals with a Lorentzian function. The extracted linewidths are $2.4(1)$ kHz and $2.5(1)$ kHz for the π and σ^+ transition and $20(1)$ kHz for the σ^- transition. The different linewidths of the spectroscopy resonances can be explained by a power broadening effect, due to the different Clebsch-Gordan coefficients of the magnetic sublevels, and the composition of the light polarization.

We use the wavemeter to determine the absolute wavenumber as

$$\bar{\nu}_{168} = 7696.955(2) \text{ cm}^{-1}. \quad (2)$$

Our measurement is consistent with the value reported in the NIST database [40] [see Eq. (1)]. The accuracy of the absolute wavenumber is limited by the wavemeter. However, our spectroscopy measurement has a precision of about 2 kHz, which provides the opportunity to improve the accuracy of the absolute frequency by several orders of magnitude using advanced measurement techniques, such as frequency combs [41].

V. LANDÉ FACTOR FOR BOSONIC ISOTOPES

From the observed Zeeman structure in the bosonic isotopes, we can extract the Landé g_J factor. This is an important quantity, e.g., to describe the atomic interaction with an external magnetic field, to describe the interaction between different atoms via their magnetic dipoles, and to benchmark

FIG. 3. (a) High-resolution spectroscopy of ^{168}Er at $B = 1.358(2)\text{ G}$, unveiling the σ^- , π , and σ^+ transition ($|m_J = -6\rangle \rightarrow |m_{J'} = -7\rangle$, $|m_J = -6\rangle \rightarrow |m_{J'} = -6\rangle$, and $|m_J = -6\rangle \rightarrow |m_{J'} = -5\rangle$). The normalized population in $|g\rangle$ is measured against the laser frequency relative to the frequency position of the π transition. (b) Measured $g_{J'}$ factor for the four bosonic isotopes for the different atomic mass numbers. The error bars denote the 1σ -standard deviation. The red solid line represents the weighted mean of the experimental data and the grey shaded area corresponds to the combined standard deviation. The black solid lines represent the $g_{J'}$ factor calculated using our semi-empirical method and the value given in the NIST database [40].

atomic spectrum calculations. Here, we use the relative frequencies of the π and σ^+ transitions to determine the value of the $g_{J'}$ factor for the excited state. In small magnetic fields, the Zeeman splitting is linear and the transition frequencies can be written as

$$\nu^\pi = \nu_0 - m_J(g_J - g_{J'})\mu_B B/h, \quad (3)$$

for the π transition and

$$\nu^{\sigma^+} = \nu_0 - [m_J g_J - (m_J + 1)g_{J'}]\mu_B B/h, \quad (4)$$

for the σ^+ transition, where ν_0 is the absolute transition frequency at $B = 0\text{ G}$, μ_B is the Bohr magneton and h is the Planck constant. By taking the difference of Eq. (4) from Eq. (3) one obtains

$$g_{J'} = \frac{(\nu^{\sigma^+} - \nu^\pi)h}{\mu_B B}, \quad (5)$$

which allows us to extract the value of $g_{J'}$, where the uncertainties are arising from the measured frequencies ν^π , ν^{σ^+} , and the applied B .

We calibrate B , before and after each spectroscopic measurement, by driving the atomic radio-frequency transition of the atoms in $|g\rangle$ from $m_J = -6 \rightarrow m_J = -5$. We evaluate possible drifts of B from these spectroscopy measurements and estimate them to be $\approx 1\text{ mG}$. This uncertainty on B

TABLE I. Isotope shifts for three bosonic isotopes in dependence of the ^{168}Er isotope. The error bars denote the statistical error, mainly given by uncertainties of B . Systematic errors are not taken into account.

isotope pair	$\nu_0 - \nu_0^{168}$ (MHz)
164–168	$-2732.290(3)$
166–168	$-1371.710(3)$
170–168	$1414.920(5)$

represents the dominant limitation on the precision of our measurements.

Figure 3(b) shows the experimentally extracted values of the $g_{J'}$ factor as a function of the isotope mass number for the four bosonic isotopes. We find that, as expected, the values for the $g_{J'}$ factor are the same within one standard deviation for all four isotopes. We combine the results by calculating the weighted mean and determine the $g_{J'}$ factor of $|e\rangle$ to

$$g_{J'} = 1.2599(5). \quad (6)$$

The individual $g_{J'}$ factors are weighted by their standard deviation and the final error corresponds to the combined 1σ standard deviation. We compare our experimentally determined $g_{J'}$ factor to the value specified in the NIST database [40], $g_{J'}^{\text{NIST}} = 1.266$, and find agreement at the 1% level. A careful study of systematic effects such as calibration errors on the magnetic field or collisional shifts (not included in the presented uncertainty) could refine this comparison further, providing a useful benchmark for atomic structure calculations.

VI. ISOTOPE SHIFT

In addition to the $g_{J'}$ factor, the high-resolution spectroscopy allows us to extract the isotope shift between the four bosonic isotopes with high precision. Because the π transition is less sensitive to magnetic field fluctuations, we fix B and, with the knowledge of the FSR, determine the relative frequency difference directly from the individual transitions. Table I gives the isotope shifts relative to the transition frequency of the ^{168}Er isotope.

At leading order, isotope shifts are caused by two effects, the field shift and the mass shift, which arise from the change of the nuclear size and the mass, respectively. Here, for the involved $4f \rightarrow 5d$ transition, both of the contributions are comparably large [42,43]. Isotope shifts of two different transitions, plotted against each other, follow at leading order a linear dependence, which is referred to as King's linearity [44]. Violations of the linearity can provide an exceptional insight into intranuclear interactions and can help to shed light on processes that are not described by the current theory of the standard model [45–50]. The availability of four isotopes that have zero nuclear spin and a large number of different narrow transitions make erbium a potential candidate for investigations along this route. In particular, erbium features further narrow transitions that involve the excitation of an electron from the $4f$ orbital to the $5d$ orbital. Consequently, in combination with our transition at 1299 nm, the nonlinearity might be less sensitive to field shifts induced by different

electron configurations and therefore interesting for future investigations [45,46,48].

VII. COHERENT CONTROL AND LIFETIME MEASUREMENTS

An important opportunity that comes along with narrow line transitions and plays a fundamental role, e.g., in quantum information and communication protocols, is the possibility to coherently control the atomic state. To demonstrate the ability to drive coherent excitations, we measure Rabi oscillations on the closed σ^- transition for a thermal cloud of the ^{168}Er isotope. We use a thermal cloud to reduce the effect of interactions, by allowing for lower densities. From theoretical calculations (see description in Sec. VIII), it is expected that the atomic polarizability of atoms in $|e\rangle$ is very low, or even negative at 1064 nm, depending on the polarization of the trapping light. Therefore, we transfer the atoms after evaporation into a crossed ODT that is created by two intersecting laser beams at 532.2 nm and 1570 nm, resulting in trap frequencies of $(\omega_x, \omega_y, \omega_z) = 2\pi[232(6), 117(7), 209(3)]$ Hz for the ground-state atoms. At this stage, we measure 2×10^4 atoms at a temperature of $T \approx 700$ nK, corresponding to a peak density of about $9 \times 12 \text{ cm}^{-3}$. After the preparation of the atomic cloud, we shine a resonant narrow-line laser with a peak intensity of about 4.9 W/cm^2 for a pulse duration of t_{pulse} onto the atomic sample and measure the atom number in $|g\rangle$ after a time of flight of 10 ms.

Figure 4(a) shows the population in $|g\rangle$, normalized to the maximum atom number as a function of t_{pulse} . We observe a damped oscillation of the population in $|g\rangle$, which is well described via $p_g(t) = 0.5e^{-t/\tau_{\text{osc}}} \cos(\Omega_R t) + 0.5$, where Ω_R is the Rabi frequency and τ_{osc} is the $1/e$ decay time of the contrast of the oscillation. We find that $\Omega_R = 2\pi \times 50.02(8)$ kHz, which corresponds to a normalized Rabi frequency of $\Omega_R^{\text{norm.}} = 2\pi \times 0.76(6)$ kHz/ $\sqrt{\text{mW/cm}^2}$. For the decay time of the contrast we find $\tau_{\text{osc}} = 192(20) \mu\text{s}$, indicating a strong decoherence mechanism. Possible mechanisms that might lead to the decoherence are, e.g. atomic interactions, intensity noise on the trapping light, intensity inhomogeneities of the probe light over the atomic cloud, or fluctuations of the magnetic field. Nonetheless, the coherent control allows us transfer atoms from $|g\rangle$ to $|e\rangle$ with an efficiency $>97\%$.

The ability to transfer atoms from $|g\rangle$ to $|e\rangle$ with high efficiency enables us to measure the lifetime of atoms in $|e\rangle$. At high densities we observe a short lifetime of the sample in $|e\rangle$, suggesting a density-dependent loss mechanism, similarly to Ref. [51]. Therefore, we reduce the atom number to $N \approx 300$ atoms by using a shorter loading time of the magneto-optical trap and we stop the evaporative cooling process at an earlier stage, leading to a temperature of $T \approx 1 \mu\text{K}$. Here, we obtain a peak number density of about $7.5 \times 10^{10} \text{ cm}^{-3}$. In this regime of low density, radiative losses dominate over few-body collisional losses.

To measure the lifetime of $|e\rangle$, we carry out two complementary measurements. First, we perform a π pulse to transfer $|g\rangle$ atoms to $|e\rangle$ with high efficiency. To obtain a pure sample of $|e\rangle$ atoms, we remove the small remaining fraction of $|g\rangle$ atoms with a resonant pulse at 401 nm. Note that, the light at 401 nm is not resonant for atoms in $|e\rangle$. We then measure the

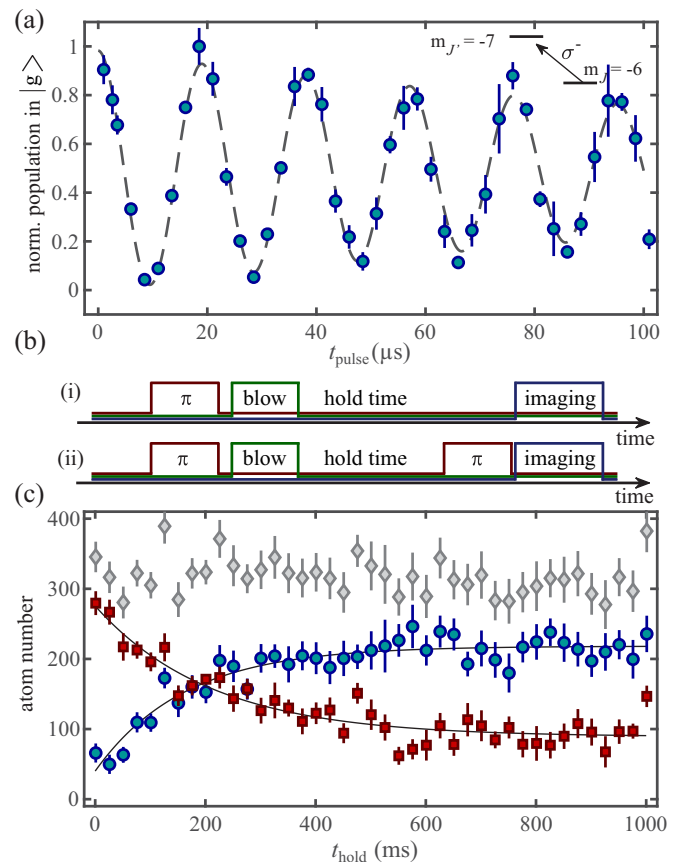

FIG. 4. (a) Coherent Rabi oscillations for ^{168}Er on the $|m_J = -6\rangle \rightarrow |m_J = -7\rangle$ transition. Shown is the normalized atom number in $|g\rangle$ against the duration of the laser pulse. The dashed line represents a fit of a damped sinusoidal oscillation to the experimental data points. (b) Schematic illustration of the two applied measurement sequences to extract state populations (see main text). (c) blue circles [red squares] represent the atom number in $|g\rangle$ [$|e\rangle$] in dependence of the hold time for the measurements sequence (i) [(ii)]. The grey diamonds represent the total atom number. The solid lines are exponential fits to the experimental data. Error bars denote the standard error of 4 (a) and 10 (c) repetitions.

lifetime of the excited sample in two independent measurements, (i) the number of atoms in $|g\rangle$, which decayed from $|e\rangle$ due to spontaneous emission, and (ii) the atomic population in $|e\rangle$ by applying a second π pulse to invert the populations in $|e\rangle$ and $|g\rangle$ in order to directly measure the excited-state atoms; see Fig. 4(b).

Figure 4(c) shows the measured atom number for both measurement sequences at different holding times t_{hold} . We observe a decay of the atom number in $|e\rangle$, which is consistent with the simultaneous growth of the atom number in $|g\rangle$. Note that, the sum of the atom number in both states remains constant over the observed timescale, indicating that atoms in $|e\rangle$, indeed, decay dominantly to $|g\rangle$. We extract the lifetime, for both measurement protocols, by fitting an exponential function $N(t) = ae^{-t/\tau_e} + d$ to the non-averaged atom numbers. Here, a denotes the amplitude and d the offset of the growth (decay) of the atom number in $|g\rangle$ ($|e\rangle$). The characteristic time τ_e represents the lifetime of $|e\rangle$. We extract a lifetime of

162(23) ms [212(33) ms] through the measurement sequence (i) [(ii)]. We combine both results by calculating the weighted mean and obtain a mean lifetime of

$$\tau_e = 178(19) \text{ ms.} \quad (7)$$

This lifetime corresponds to a natural linewidth of 0.9(1) Hz, which is in agreement within error bars with the theoretical predicted value of 2(1) Hz in Ref. [23]. Note that, the measured lifetime is consistent with the natural linewidth predicted from Ω_R determined above.

VIII. THEORETICAL PREDICTIONS

We compare our experimental findings with the results of a semi-empirical model, which has previously been very successful in predicting the properties of broader optical transitions in erbium and dysprosium [52,53]. Our calculations are based on the semi-empirical method provided by the COWAN suite of codes [54,55], and extended by us [52]. In a first step, *ab initio* radial wave functions $P_{n\ell}$ for all the subshells $n\ell$ of the considered configurations, with n and ℓ being the principal and orbital quantum numbers, are computed with the relativistic Hartree-Fock (HFR) method. Those wave functions are then used to calculate energy parameters that are the building blocks of the atomic Hamiltonian. In a second step, the energy parameters are adjusted so that the eigenvalues of the Hamiltonian best fit the experimental energies of the NIST database [40], using Kramida's version of the least-square fitting COWAN code RCE [55]. The $P_{n\ell}$ wave functions also serve to calculate the mono-electronic transition integrals $\langle n\ell|r|n'\ell'\rangle = \int dr P_{n\ell}(r)rP_{n'\ell'}(r)$, that are the building blocks of Einstein coefficients for spontaneous emission A_{ik} . In a third step, the $\langle n\ell|r|n'\ell'\rangle$ integrals are adjusted to minimize the difference between experimental and theoretical A_{ik} coefficients [52].

For the even-parity levels of erbium, we use the same energy parameters as Ref. [56]. Briefly, the even electronic configurations are separated into three groups:

$$4f^{12}6s^2 + 4f^{12}5d6s + 4f^{11}6s^26p,$$

$$4f^{12}6s^2 + 4f^{11}5d6s6p,$$

and

$$4f^{12}6s^2 + 4f^{12}6s7s + 4f^{12}6s6d + 4f^{12}6p^2.$$

Each group is associated with a different least-square fitting calculation with experimental levels belonging to the corresponding configurations.

Compared to Refs. [56,57], the odd-parity level calculations have been improved by adding some high-lying experimental energy levels that were previously excluded from the fitting procedure, as well as incorporating a larger number of free configuration-interaction parameters into the fitting procedure. The following configurations are included in the calculation: $4f^{11}5d6s^2$, $4f^{11}5d^26s$, $4f^{12}6s6p$, $4f^{12}5d6p$, and $4f^{13}6s$. The latter is included for technical purpose, but does not play a physical role. The fitting procedure is performed using a total of 30 free groups of parameters and 219 levels. The standard deviation between experimental and calculated energies is equal to 53 cm^{-1} , which is satisfactory

for a semi-empirical calculation. Details on the parameters for the first four odd parity configurations are given in the Appendix.

The $\langle n\ell|r|n'\ell'\rangle$ transition integrals were adjusted using the set of experimental A_{ik} coefficients of Ref. [58], especially the transitions involving levels of the ground-state configuration $[\text{Xe}]4f^{12}6s^2$. Following Ref. [52], we seek to minimize the standard deviation σ_A on Einstein coefficients A_{ik} [52]. Because the latter is poorly sensitive to $\langle 4f|r|5d\rangle$, we could not find a value of that integral minimizing σ_A , we have taken a scaling factor with respect to the HFR integral equal to $f_{4f,5d} = 0.95$, following previous works on dysprosium [53] and holmium [59]. We applied the fitting procedure on $\langle 6s|r|6p\rangle$, and found $f_{6s,6p} = 0.786$. We have fitted 77 experimental lines and found a standard deviation $\sigma_A = 8.085 \times 10^6 \text{ s}^{-1}$.

With this optimized set of energies and transition integrals, we have calculated the polarizabilities of the ground and excited states using the sum-over-state formula coming from second-order perturbation theory. The polarizability of the excited level also depends on $\langle 5d|r|6p\rangle$, for which we took a scaling factor of 0.8.

From our theory we obtain a wavenumber of $\bar{\nu}^{\text{th}} = 7729.3 \text{ cm}^{-1}$, a g_J factor of $g_J^{\text{th}} = 1.2622$, and an excited-state lifetime of $\tau^{\text{th}} = 602 \text{ ms}$. For $\bar{\nu}^{\text{th}}$ and g_J^{th} we find satisfactory agreement with the values reported from the current experimental work. Note that, by included least-square fitted energy parameters in the theoretical calculations (compared with Ref. [60]), we obtain better agreement with the experimental data. The extracted lifetime is about a factor of 3 longer compared to the experimentally measured value. This discrepancy comes from the fact that the underlying transition dipole moment involves small components in the eigenvector associated with level $|e\rangle$. Those small components are more difficult to optimize, as they are less affected by the least-square fitting procedure on energies.

Figure 5(a) shows the calculated atomic polarizability $\alpha(\omega)$ for $|e\rangle$ in a broad wavelength range from 350 nm to 1500 nm. The polarizability spectrum becomes very dense at lower wavelengths. The background value of $\alpha(\omega)$ is dominantly positive; however, a strong transition at around 1140 nm causes a negative value of $\alpha(\omega)$ around 1064 nm, commonly used for optical dipole traps. Further, this strong transition creates two interesting situations appearing at 1010 nm and 1070 nm. Here, while $\alpha(\omega)$ is finite for $|g\rangle$, $\alpha(\omega)$ of $|e\rangle$ is either 0 (1010 nm) or has the same absolute value with opposite sign (1070 nm). These circumstances are beneficial for the realization of spin-dependent lattice configurations [61]. Due to the weak coupling to $|g\rangle$, the effect of the transition at 1299 nm is not visible in this plotting range.

IX. MAGIC-WAVELENGTH CONDITIONS

A very important ingredient for the coherent control of our two-level system is the atomic polarizability of each state, $\alpha(\omega)$, and their ratio $\alpha_{|e\rangle}/\alpha_{|g\rangle}$. Figures 5(b)–5(d) show examples of interesting wavelength regions in which, for a given light polarization (π), the $|g\rangle$ and $|e\rangle$ state polarizabilities cross, meaning that atoms in both states will experience the same optical trapping potential. These specific values of the

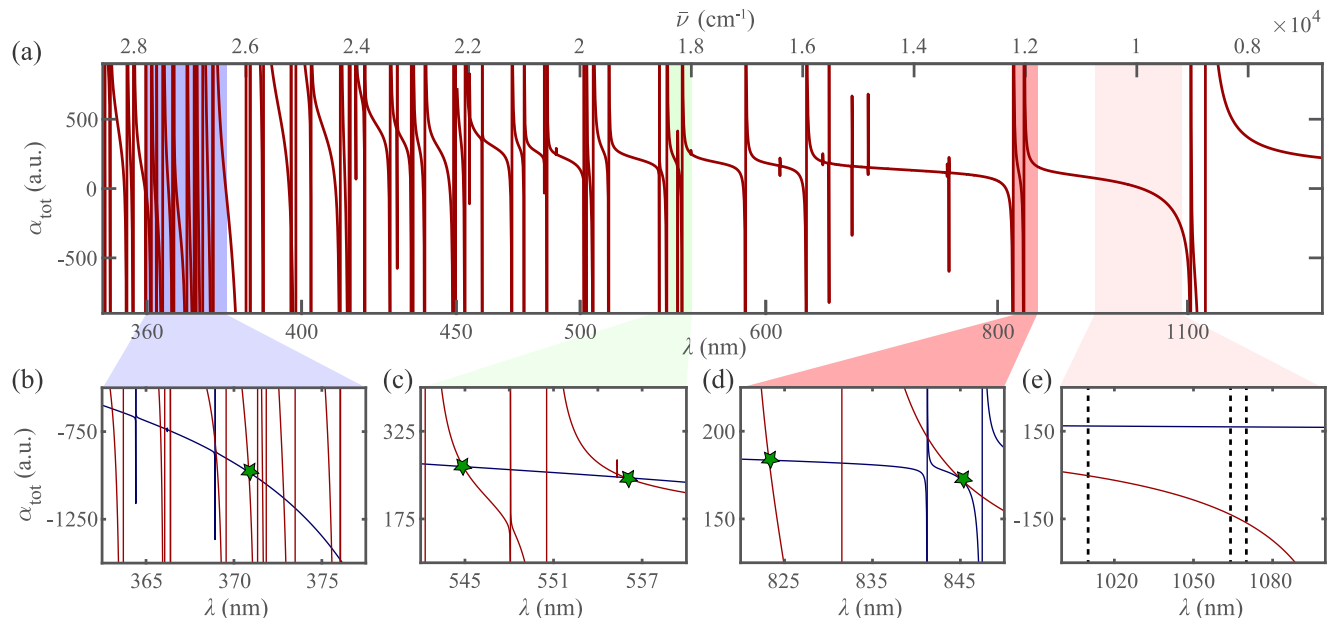

FIG. 5. (a) Theoretically calculated $\alpha(\omega)$ for $|e\rangle$ as a function of the wavelength λ for π -polarized light. [(b)–(e)] Zoom-in into specific wavelength regions showing $\alpha(\omega)$ for $|e\rangle$ (red) and $|g\rangle$ (blue). The green stars indicate possible magic wavelengths. The dashed black lines in (e) denote the wavelength of 1010 nm, 1064 nm, and 1070 nm.

wavelength realize the so-called *magic* condition. Our calculation shows wavelength values for which both red-detuned [Figs. 5(c) and 5(d)] or blue detuned magic [Fig. 5(b)] trapping is possible. Moreover, Fig. 5(e) shows a case in which the polarizability of $|g\rangle$ and $|e\rangle$ has opposite sign. This situation might be interesting to create an effectively subwavelength lattice in which $|g\rangle$ and $|e\rangle$ atoms are spaced by $\lambda/4$.

The existence of such type of crossings is a rather general feature also in more simpler atomic species. Additionally, $\alpha_{|e\rangle}/\alpha_{|g\rangle}$, and thus the exact crossing position, can be tuned by changing the light polarization or the magnetic-field orientation [56,62–64]. These features, named in analogy “magic”-polarization condition [64,65], originate from the vectorial and tensorial part of the atomic polarizability, following the equation:

$$\alpha(\omega) = \alpha_s(\omega) + i \frac{[\mathbf{u}^* \times \mathbf{u}] \cdot \mathbf{J}}{2J} \alpha_v(\omega) + \frac{J(J+1) - 3m_j^2}{J(2J-1)} \frac{1 - 3\cos^2\theta_p}{2} \alpha_t(\omega). \quad (8)$$

Here, $\alpha_s(\omega)$, $\alpha_v(\omega)$, and $\alpha_t(\omega)$ are the scalar, the vectorial, and the tensorial polarizabilities and \mathbf{u} is the polarization vector of the laser field. The angle θ_p defines the orientation of \mathbf{u} with respect to \mathbf{B} .

We aim at exploring the impact of the vectorial polarizability on $\alpha_{|e\rangle}/\alpha_{|g\rangle}$ for a commonly used trapping wavelength of 532.2 nm. As for Sec. VII, we prepare our $|g\rangle$ atoms in a crossed optical dipole trap, with a horizontal (vertical) beam operating at 532.2 nm (1570 nm). For reference, we first excite the center-of-mass (COM) motion and extract the vertical trap frequency (mainly determined by the light at 532.2 nm) of the atoms in $|g\rangle$; see Fig. 6(a). We then repeat the same trap-frequency measurements for atoms in $|e\rangle$ and use the relation of $\alpha_{|e\rangle}/\alpha_{|g\rangle} = (\omega_{|e\rangle}/\omega_{|g\rangle})^2$ [63].

To study the impact of the vectorial polarizability, we measure $\alpha_{|e\rangle}/\alpha_{|g\rangle}$ for different polarization of the light at 532.2 nm. In each measurement, $\theta_p = 90^\circ$, while the angle ϕ defining \mathbf{u} is varied [66]; see inset in Fig. 6(b). Figure 6(b) summarizes our results. We observe a periodic behavior of $\alpha_{|e\rangle}/\alpha_{|g\rangle}$ as a function of ϕ , which reaches its maximum for σ^- -polarized light ($\phi = 45^\circ$). At this angle, we find $\alpha_{|e\rangle}/\alpha_{|g\rangle} = 0.98(3)$, which is consistent within the experimental uncertainty to the magic-trapping condition. The figure also shows our theoretical calculation, which qualitatively reproduces the experimental values, although with a smaller amplitude, which might indicate a shift of the close by transition as well as an underestimation of the transition strength. At $\phi = 45^\circ$, the theory gives $(\alpha_{|e\rangle}/\alpha_{|g\rangle})_{\text{theo}} = 0.97$, and predicts crossings at 528.9 nm and 532.5 nm, which are interesting options to explore with tunable laser systems. The polarizabilities for the special cases of σ^- - and σ^+ -polarized light are shown in Fig. 6 for an extended wavelength region.

We estimate from our theoretical calculations, that the relative change of $\alpha_{|e\rangle} - \alpha_{|g\rangle}$ for $\phi = 45^\circ$, in linear approximation, follows a slope of about 4 a. u./nm at 528.9 nm and a slope of about 80 a. u./nm at 532.5 nm. This implies that a sufficient laser stability to resolve our observed linewidth can be reached with standard laser locking techniques. Further, the measured BEC lifetime at 532.2 nm is about 2 s, which suggests a low photon scattering rate. Furthermore, as the detuning to the nearby ground-state transition is increased, for the crossing at 528.9 nm a potentially lower scattering rate can be found [see Fig. 6(c)].

X. CONCLUSION

In conclusion, we have observed the narrow inner-shell orbital transition at 1299 nm for the four bosonic, as well as for the fermionic isotope. We characterized the transition

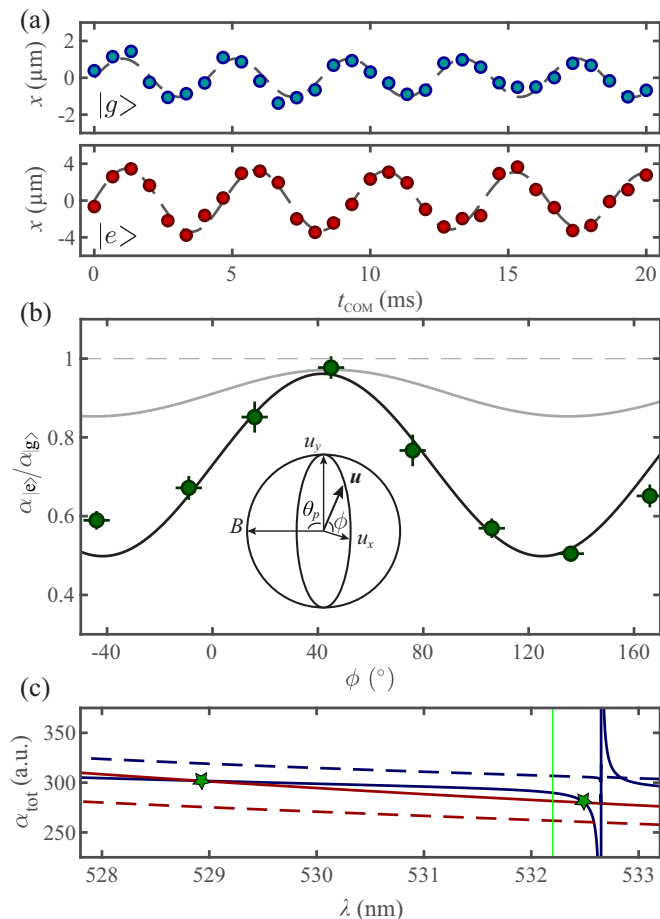

FIG. 6. (a) Center position of the thermal cloud in dependence of the hold time for $|g\rangle$ (blue) and $|e\rangle$ (red) for the case of linearly polarized light with \mathbf{u} pointing along y and \mathbf{B} aligned opposite to the propagation axis of the 532.2 nm trapping light. Atoms are transferred to $|e\rangle$ following the protocol (ii) described in Sec. VII. (b) Polarizability ratio $\alpha_{|e\rangle}/\alpha_{|g\rangle}$ for different polarizations of the trapping light defined by the angle ϕ between \mathbf{u} and the optical axis of the $\lambda/4$ -waveplate. The black solid line is a guide to the eye based on a sinusoidal fit to the experimental data and the grey solid line represents theoretical results obtained from the sum-over-states method. The inset illustrates the experimental configuration for the shown data. (c) Theoretically calculated $\alpha(\omega)$ for $|e\rangle$ (red) and $|g\rangle$ (blue) in their lowest magnetic sublevels as a function of the wavelength λ for σ^- (solid line) and σ^+ -polarized (dashed line) light. The green solid line indicates the wavelength for the measurement in (b) and the green stars indicate possible magic wavelengths for σ^- -polarized light.

by measuring the g_F factor and the atomic polarizability at 532.2 nm, which we compare to a semi-empirical model. Further, we demonstrated the ability to coherently control the atomic state. The narrow transition, at a wavelength within the telecom window, with a linewidth of 0.9(1) Hz and a related long lifetime of 178(19) ms, represents a very versatile tool with outstanding potential for a broad range of possible applications.

For the realization of efficient long-distance quantum communication, atom-photon interfaces at wavelengths that are compatible with telecom wavelengths are highly desired [29–31]. To date, most of the existing approaches rely either

on frequency conversion of the photons [67,68], leading to undesired noise and reduced efficiency, or suffer from various other dephasing mechanisms [69,70]. Here, our transition at 1299 nm, lying within the O-band of the telecom wavelength architecture, is a potential candidate to circumvent these issues. Finally, the photon storage time can be drastically improved by collective scattering in ordered atomic arrays, exceeding the natural lifetime [71,72].

The relatively long wavelength of this transition may also provide a favorable platform for studies of collective scattering from ordered atomic samples. Such effects, which include geometry-dependent enhancement or suppression of emission [73,74], can be more significant when the spacing between atoms is small relative to the transition wavelength. For our 266 nm spacing, typical of lattice confinement with 532 nm light [75], this condition is well met in our system, in contrast to the more common situation present in alkaline atoms where the wavelength of trapping light typically exceeds the wavelength of the scattering transition.

Additionally, the advantages of encoding qubits in the ground and the metastable state and the possibility for independent control of atomic motions by lattice light is promising for quantum computational tasks [20–22]. Moreover, the contact interaction can be tuned using the technique of a narrow-line optical Feshbach resonance, where the system suffers only weak atom loss [7–9].

Finally, this transition enables the coherent control of magnetic Zeeman levels for dipolar bosonic atoms, which has been elusive so far, due to the absent hyperfine interactions [76]. The 13 magnetic Zeeman levels in the ground state of erbium

can be employed as spin states and allow for the realization of large bosonic spin systems with dipolar interactions. In combination with optical lattices, this enables the possibility to study many-body dynamics in extended Bose-Hubbard models [77,78]. Generally, in such large spin systems, the long lifetime of the excited state is helpful for the realization of advanced, spin-resolved imaging-shelving techniques [79,80].

APPENDIX

Odd-parity energy parameters

Here we present the parameters of the first four odd-parity configurations of neutral erbium. The ones of the $4f^{13}6s$ configuration are not shown, as the latter does not play any physical role in the level interpretation.

Tables II and III show the one-configuration parameters, like the direct F^k , exchange G^k , or spin-orbit ζ_{nl} integrals. Table IV shows the configuration-interaction ones. We also give the scaling factor $f_X = X_{\text{fit}}/X_{\text{HFR}}$ between the fitted and *ab initio* value of the parameter X . During the fitting procedure, some groups of parameters are constrained to vary within the same scaling factors; such groups are characterized by the same $f_X = r_n$ value in the second column of Tables II–IV. The word “fix” means that the corresponding parameters are not adjusted. Finally, we use so-called “effective” parameters, like α , β , γ , or $F_1(4f5d)$, which cannot be calculated *ab initio*, but which are there to compensate the absence of electronic configurations not included in the model. Their initial values are known from previous studies.

TABLE IV. Configuration-interaction parameters: parameter names, constraints (see text), fitted values and scaling factors $f_X = X_{\text{fit}}/X_{\text{HFR}}$, for odd-parity configuration pairs of neutral Er. All parameters are in cm^{-1} .
