The low-temperature unitary Bose gas is a fundamental paradigm in few-body and many-body physics, attracting wide theoretical and experimental interest. Here, we present experiments performed with unitary ^{133}Cs and ^{7}Li atoms in two different setups, which enable quantitative comparison of the three-body recombination rate in the low-temperature domain. We develop a theoretical model that describes the dynamic competition between two-body evaporation and three-body recombination in a harmonically trapped unitary atomic gas above the condensation temperature. We identify a universal "magic" trap depth where, within some parameter range, evaporative cooling is balanced by recombination heating and the gas temperature stays constant. Our model is developed for the usual three-dimensional evaporation regime as well as the two-dimensional evaporation case, and it fully supports our experimental findings. Combined ^{133}Cs and ^{7}Li experimental data allow investigations of loss dynamics over 2 orders of magnitude in temperature and 4 orders of magnitude in three-body loss rate. We confirm the $1/T^2$ temperature universality law. In particular, we measure, for the first time, the Efimov inelasticity parameter $\eta_* = 0.098(7)$ for the 47.8-G d-wave Feshbach resonance in ^{133}Cs. Our result supports the universal loss dynamics of trapped unitary Bose gases up to a single parameter η_*.

Subject Areas: Atomic and Molecular Physics

I. INTRODUCTION

Resonantly interacting Bose systems realized in ultracold atomic gases are attracting growing attention thanks to being among the most fundamental systems in nature and also among the least studied. Recent theoretical studies have included hypothetical BEC-BCS–type transitions [1–5] and, at unitarity, calculations of the universal constant connecting the total energy of the system with the only energy scale left when the scattering length diverges: $E_n = \hbar^2 n^{2/3}/m$ [6–9]. The latter assumption itself remains a hypothesis as the Efimov effect might break the continuous scaling invariance of the unitary Bose gas and introduce another relevant energy scale to the problem. A rich phase diagram of the hypothetical unitary Bose gas at finite temperature has also been predicted [10,11].

In experiments, several advances in the study of the resonantly interacting Bose gas have recently been made using the tunability of the s-wave scattering length a near a Feshbach resonance. The JILA group showed signatures of beyond-mean-field effects in two-photon Bragg spectroscopy performed on a ^{85}Rb BEC [12], and the ENS group quantitatively studied the beyond-mean-field Lee-Huang-Yang corrections to the ground-state energy of the Bose-Einstein condensate [13]. Logarithmic behavior of a strongly interacting two-dimensional (2D) superfluid was also reported by the Chicago group [14]. Experiments have also started to probe the regime of unitarity ($1/a = 0$) directly. Three-body recombination rates in the nondegenerate regime have been measured in two different species, ^{7}Li [15] and ^{39}K [16], and they clarified the temperature dependence of the unitary Bose gas lifetime. In another experiment, fast and nonadiabatic projection of the BEC on the regime of unitarity revealed the establishment of thermal quasiequilibrium on a time scale faster than inelastic losses [17].

In a three-body recombination process, three atoms collide and form a dimer, the binding energy of which is transferred into kinetic energies of the colliding partners. The binding energy is usually larger than the trap depth and thus leads to the loss of all three atoms. Because three-body recombination occurs more frequently at the center of the trap, this process is associated with "anti-evaporative" heating (loss of atoms with small potential energy) which competes with two-body evaporation and leads to a non-trivial time dependence for the sample temperature.

In this article, we analyze the loss dynamics of ^{133}Cs and ^{7}Li unitary Bose gases prepared at various temperatures and atom numbers. We develop a theoretical model that describes these atom loss dynamics. By simultaneously taking into account two- and three-body losses, we quantitatively determine each of these contributions. Our analysis covers both the case of three-dimensional evaporation, which applies to our ^{133}Cs experimental data, and two-dimensional evaporation, which applies to the ^{7}Li data. In both cases, we find the existence of a "magic" value for the trap-depth-over-temperature ratio, where residual evaporation compensates for three-body loss heating and maintains the gas temperature constant within some range of parameters. Comparing measurements in these two atomic species, we find the dynamics to be universal; i.e., in both systems, the three-body loss rate is found to scale universally with temperature. Excellent agreement between theory and experiment confirms that the dynamic evolution of the unitary Bose gas above the condensation temperature can be well modeled by the combination of two- and three-body interaction processes.

II. EXPERIMENTS

In this section, we present experimental $T(N)$ trajectories of unitary ^{133}Cs and ^{7}Li Bose gases trapped in shallow potentials with non-negligible evaporation, where T is the cloud temperature and N the atom number. We initially prepare the samples at temperature T_{in} and atom number N_{in} in a trap of depth U, as described in Appendix A. We measure the atom numbers and the temperatures from *in situ* absorption images taken after a variable hold time t.

The ^{133}Cs Feshbach resonance at 47.8 Gauss and the ^{7}Li Feshbach resonance at 737.8 Gauss used in the experiments have very similar resonance strength parameters $s_{res} = 0.67$ and 0.80, respectively [18,19], and are in the intermediate coupling regime (neither in the broad nor narrow resonance regime). We note that in the ^{133}Cs case, the dimer state giving rise to the Feshbach resonance is of d-wave nature. Both the two-body and three-body collisions happen in the s-wave channel; we therefore expect to observe universal Efimov (s-wave) physics.

In Fig. 1(a), we present typical results for the evolution $T(N)$ in the case of ^{133}Cs. We show trajectories for different initial relative trap depths $\eta_{in} = U/k_B T_{in}$, where k_B is Boltzmann's constant. We also plot the relative temperature

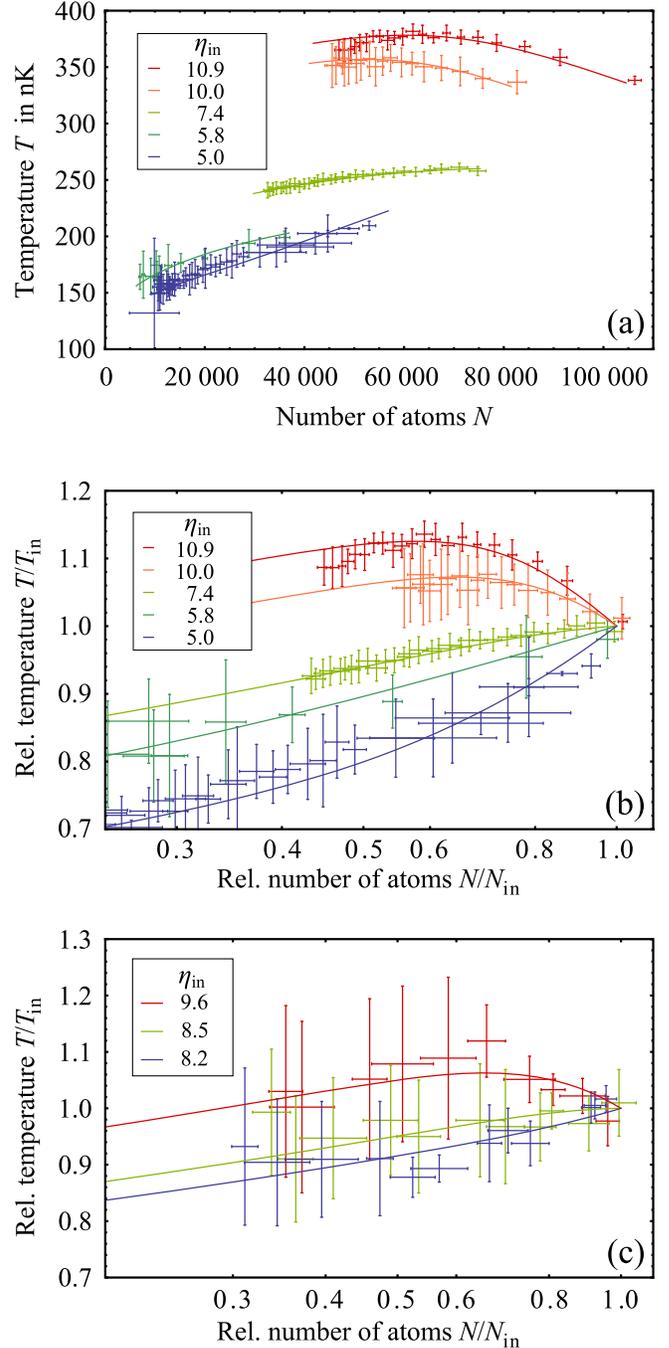

FIG. 1. Evolution of the unitary ^{133}Cs gas in (a) absolute and (b) relative numbers (points). The solid lines are fits of the data using the theory presented in Sec. III, and the fitted initial relative trap depth $\eta_{in} = U/k_B T_{in}$ is given in the legend. The condition for $(dT/dN)|_{t=0}$ is expected for $\eta_{in} \approx \eta_m \approx 8.2$, very close to the measured data for $\eta_{in} = 7.4$ [green lines in (a) and (b)]. (c) Evolution of the unitary ^{7}Li gas. The solid lines are fits of the data using our 2D evaporation model and the fitted initial relative trap depth η_{in} as in (b). In 2D evaporation, $\eta_{in} \approx \eta_m^{eff} = \eta_m + 1 = 8.5$ is required to meet the $(dT/dN)|_{t=0}$ condition and is found to be in good agreement with the measured value 8.5 [green line in (c)]; see text. All error bars represent 1 standard deviation.

$T/T_{\rm in}$ as a function of the relative atom number $N/N_{\rm in}$ for the same data in Fig. 1(b), and for ^{7}Li in Fig. 1(c). Each data point results from averaging about ten $\{N(t), T(t)\}$ measurements at a given t, and error bars are 1 standard deviation from the mean.

The readily observed maxima in the $T - N$ plots indicate deviation from the usually applied model for three-body recombination loss of atoms and "anti-evaporation" heating associated with it [20]. This model is valid in the limit of deep trapping potentials (trapping depth much larger than the gas temperature) and for temperature-independent losses. We show below that the additional dynamics come from the two-body evaporation due to the finite trap depth. In order to analyze the observed data quantitatively, and to correctly extract the three-body recombination loss rate constant, we now describe our theoretical model which generalizes the study [20] to arbitrary trap depths.

III. THEORETICAL MODEL

A. Rate equation for atom number

The locally defined three-body recombination rate $L_3 n^3(\mathbf{r})/3$ leads, through integration over the whole volume, to the loss rate of atoms:

$$\dot{N} = -3 \int \frac{L_3 n^3(\mathbf{r})}{3} d^3\mathbf{r} = -L_3 \langle n^2 \rangle N, \qquad (1)$$

where the factor of 3 in front of the integral reflects the fact that all 3 atoms are lost per each recombination event. In the following, we neglect single-atom losses due to collisions with the background gas, and we assume that two-body inelastic collisions are forbidden, a condition that is fulfilled for atoms polarized in the absolute ground state.

An expression for the three-body recombination loss coefficient at unitarity for a nondegenerate gas has been developed in Ref. [15]. Averaged over the thermal distribution, it reads

$$L_3 = \frac{72\sqrt{3}\pi^2 \hbar (1 - e^{-4\eta_*})}{m k_{\rm th}^6}$$
$$\times \int_0^\infty \frac{(1 - |s_{11}|^2) e^{-k^2/k_{\rm th}^2} k \, dk}{|1 + (kR_0)^{-2is_0} e^{-2\eta_*} s_{11}|^2}, \qquad (2)$$

where $k_{\rm th} = \sqrt{m k_{\rm B} T}/\hbar$, R_0 is the three-body parameter, and the Efimov inelasticity parameter η_* characterizes the strength of the short-range inelastic processes. Here, $\hbar$ is the reduced Planck's constant, and $s_0 = 1.00624$ for three identical bosons [21]. The matrix element s_{11} relates the incoming to outgoing wave amplitudes in the Efimov scattering channel and shows the emerging discrete scaling symmetry in the problem (see, for example, Ref. [22]). Details are given in the supplementary material to Ref. [15] for the calculation of $s_{11}(ka)$, where a is the scattering

length and k is the relative wave number of the colliding partners. Because of its numerically small value for three identical bosons at unitarity, we can set $|s_{11}| = 0$, and L_3 is well approximated by

$$L_3 \approx \frac{\hbar^5}{m^3} 36\sqrt{3}\pi^2 \frac{1 - e^{-4\eta_*}}{(k_{\rm B} T)^2} = \frac{\lambda_3}{T^2}, \qquad (3)$$

where λ_3 is a temperature-independent constant. Assuming a harmonic trapping potential, we directly express the average square density $\langle n^2 \rangle$ through N and T. In combination with Eq. (3), Eq. (1) is represented as

$$\dot{N} = -\gamma_3 \frac{N^3}{T^5}, \qquad (4)$$

where

$$\gamma_3 = \lambda_3 \left(\frac{m\bar{\omega}^2}{2\sqrt{3}\pi k_{\rm B}} \right)^3, \qquad (5)$$

with $\bar{\omega}$ being the geometric mean of the angular frequencies in the trap.

To model the loss of atoms induced by evaporation, we consider time evolution of the phase-space density distribution of a classical gas:

$$f(\mathbf{r}, \mathbf{p}) = \frac{n_0 \lambda_{\rm dB}^3}{(2\pi\hbar)^3} e^{-U(\mathbf{r})/k_{\rm B} T} e^{-\mathbf{p}^2/2m k_{\rm B} T}, \qquad (6)$$

which obeys the Boltzmann equation. Here, n_0 is the central peak density of atoms, $\lambda_{\rm dB} = (2\pi\hbar^2/m k_{\rm B} T)^{1/2}$ is the thermal de Broglie wavelength, and $U(\mathbf{r})$ is the external trapping potential. The normalization constant is fixed by the total number of atoms, such that $\int f(\mathbf{r}, \mathbf{p}) d^3\mathbf{p} d^3\mathbf{r} = N$.

If the gas is trapped in a three-dimensional (3D) trap with a potential depth U, the collision integral in the Boltzmann equation can be evaluated analytically [23]. Indeed, the low-energy collisional cross section

$$\sigma(k) = \frac{8\pi}{k^2 + a^{-2}} \qquad (7)$$

reduces at unitarity to a simple dependence on the relative momentum of colliding partners: $\sigma(k) = 8\pi/k^2$. However, not every collision leads to a loss of atoms due to evaporation. Consider

$$\eta = U/k_{\rm B} T. \qquad (8)$$

In the case of $\eta \gg 1$, such loss is associated with a transfer of a large amount of energy to the atom, which ultimately leads to the energy-independent cross section. This can be understood with a simple argument [24]. Assume that two atoms collide with the initial momenta $\mathbf{p}_1$ and $\mathbf{p}_2$. After the collision, they emerge with the momenta $\mathbf{p}_3$ and $\mathbf{p}_4$, and if

one of them acquires a momentum $|\mathbf{p}_3| \gtrsim \sqrt{2mU}$, the momentum $|\mathbf{p}_4|$ is necessarily smaller than the most probable momentum of atoms in the gas and $|\mathbf{p}_3| \gg |\mathbf{p}_4|$. In the center-of-mass coordinates, the absolute value of the relative momentum is preserved, so $\frac{1}{2}|\mathbf{p}_1 - \mathbf{p}_2| = \frac{1}{2}|\mathbf{p}_3 - \mathbf{p}_4| \approx \frac{1}{2}|\mathbf{p}_3|$. Assuming $|\mathbf{p}_3| = \sqrt{2mU}$, we get $|\mathbf{p}_1 - \mathbf{p}_2| = \sqrt{2mU}$. Substituting the relative momentum in the center-of-mass coordinate, $\hbar\mathbf{k} = \frac{1}{2}(\mathbf{p}_1 - \mathbf{p}_2)$, into the unitary form of the collisional cross section, we find that the latter is energy independent:

$$\sigma_U = \frac{16\pi\hbar^2}{mU}, \tag{9}$$

and the rate equation for the atom number can be written as

$$\dot{N} = -\Gamma_{\text{ev}} N, \qquad \Gamma_{\text{ev}} = n_0 \sigma_U \bar{v} e^{-\eta} \frac{V_{\text{ev}}}{V_{\text{e}}}. \tag{10}$$

The peak density is $n_0 = N/V_{\text{e}}$, where V_{e} is the effective volume of the sample. In the harmonic trap, V_{e} can be related to $\bar{\omega}$ and the temperature T: $V_{\text{e}} = (2\pi k_B T/m\bar{\omega}^2)^{3/2}$. The ratio of the evaporative and effective volumes is defined by [23]

$$\frac{V_{\text{ev}}}{V_{\text{e}}} = \eta - 4(3,\eta)\frac{P(a+1,\eta)}{P(a,\eta)}, \tag{11}$$

where $P(a,\eta)$ is the incomplete Gamma function

$$P(a,\eta) = \frac{\int_0^\eta u^{a-1} e^{-u} du}{\int_0^\infty u^{a-1} e^{-u} du}.$$

Finally, taking into account both three-body recombination loss [see Eqs. (4) and (5)] and evaporative loss, we can express the total atom number loss rate equation as

$$\dot{N} = -\gamma_3 \frac{N^3}{T^5} - \gamma_2 e^{-\eta} \frac{V_{\text{ev}}}{V_{\text{e}}} \frac{N^2}{T}, \tag{12}$$

where

$$\gamma_2 = \frac{16}{\pi} \frac{\hbar^2 \bar{\omega}^3}{k_B U}. \tag{13}$$

Note that η and the ratio of the evaporative and effective volumes explicitly depend on temperature, and γ_2 is temperature independent.

B. Rate equation for temperature

1. Anti-evaporation and recombination heating

Reference [20] points out that in each three-body recombination event, a loss of an atom is associated with an excess of $k_B T$ of energy that remains in the sample.

This mechanism is caused by the fact that recombination events occur mainly at the center of the trap, where the density of atoms is highest, and it is known as anti-evaporation heating. We now show that the unitary limit is more anti-evaporative than the regime of finite scattering lengths considered in Ref. [20], where L_3 is temperature independent. We separate center-of-mass and relative motions of the colliding atoms and express the total loss of energy per three-body recombination event as follows:

$$\dot{E}_{3b} = -\int \left\{ \frac{L_3 n^3(\mathbf{r})}{3} (\langle E_{\text{cm}} \rangle + 3U(\mathbf{r})) \right. \\ \left. + \frac{n^3(\mathbf{r})}{3} \langle L_3(k) E_k \rangle \right\} d^3\mathbf{r}. \tag{14}$$

The first two terms in parentheses represent the mean center-of-mass kinetic energy $\langle E_{\text{cm}} \rangle = \langle P_{\text{cm}}^2 \rangle / 2M$ and the local potential energy $3U(\mathbf{r})$ per each recombination triple. $M = 3m$ is the total mass of the three-body system. The last term stands for thermal averaging of the three-body coefficient over the relative kinetic energy $E_k = (\hbar k)^2/2\mu$, where μ is the reduced mass.

Averaging the kinetic energy of the center-of-mass motion over the phase-space density distribution [Eq. (6)] gives $\langle E_{\text{cm}} \rangle = (3/2)k_B T$. Then, the integration over this term is straightforward, and using Eq. (1), we have

$$-\int \frac{L_3 n^3(\mathbf{r})}{3} \langle E_{\text{cm}} \rangle d^3\mathbf{r} = \frac{1}{2} k_B T \dot{N}. \tag{15}$$

The integration over the second term can be easily evaluated as well:

$$-\int \frac{3L_3}{3} n^3(\mathbf{r}) U(\mathbf{r}) d^3\mathbf{r} = \frac{1}{2} k_B T \dot{N}. \tag{16}$$

To evaluate the third term, we recall the averaged over the thermal distribution expression of the three-body recombination rate in Eq. (2). Now, its integrand has to be supplemented with the loss of the relative kinetic energy per recombination event E_k. Keeping the limit of Eq. (3), this averaging can be easily evaluated to give $\langle L_3(k) E_k \rangle = L_3 k_B T$. Finally, the last term in Eq. (14) gives

$$-\int \frac{n^3(\mathbf{r})}{3} \langle L_3(k) E_k \rangle d^3\mathbf{r} = \frac{1}{3} k_B T \dot{N}. \tag{17}$$

Finally, getting together all the terms, the lost energy per lost atom in a three-body recombination event becomes

$$\frac{\dot{E}_{3b}}{\dot{N}} = \frac{4}{3} k_B T. \tag{18}$$

This expression shows that the unitarity limit is more anti-evaporative than the regime of finite scattering length

$(k|a| \leq 1)$. As the mean energy per atom in the harmonic trap is $3k_BT$, at unitarity each escaped atom leaves behind $(3 - 4/3)k_BT = (5/3)k_BT$ of the excess energy as compared to $1k_BT$ when L_3 is energy independent. In the latter case, thermal averaging of the relative kinetic energy gives $\langle E_k \rangle = 3k_BT$, and thus $\dot{E}_{3b}/\dot{N} = 2k_BT$.

Equation (18) is readily transformed into the rate equation for the rise of temperature per lost atom using the fact that $E_{3b} = 3Nk_BT$ in the harmonic trap and Eq. (4):

$$\dot{T} = \frac{5}{3}\frac{T}{3}\gamma_3\frac{N^2}{T^5}. \qquad (19)$$

Another heating mechanism pointed out in Ref. [20] is associated with the creation of weakly bound dimers whose binding energy is smaller than the depth of the potential. In such a case, the three-body recombination products stay in the trap, and the binding energy is converted into heat.

In the unitary limit, this mechanism causes no heating. In fact, in this regime, as shown in the supplementary material to Ref. [15], the atoms and dimers are in chemical equilibrium with each other; e.g., the rate of dimer formation is equal to the dissociation rate. We therefore exclude this mechanism from our considerations.

2. Evaporative cooling

"Anti-evaporative" heating can be compensated by evaporative cooling. The energy loss per evaporated atom is expressed as

$$\dot{E} = \dot{N}(\eta + \tilde{\kappa})k_BT, \qquad (20)$$

where $\tilde{\kappa}$ in a harmonic trap is [23]

$$\tilde{\kappa} = 1 - \frac{P(5,\eta)}{P(3,\eta)}\frac{V_e}{V_{ev}}, \qquad (21)$$

with $0 < \tilde{\kappa} < 1$.

In a harmonic trap, the average energy per atom is $3k_BT = (E/N)$. Taking the derivative of this equation and combining it with Eq. (20), we get

$$3\frac{\dot{T}}{T} = \frac{\dot{N}}{N}(\eta + \tilde{\kappa} - 3). \qquad (22)$$

From Eqs. (10) and (22), evaporative cooling is expressed as

$$\dot{T} = -\gamma_2 e^{-\eta}\frac{V_{ev}}{V_e}(\eta + \tilde{\kappa} - 3)\frac{N}{T}\frac{T}{3}, \qquad (23)$$

where, as before, the temperature dependence remains in η.

Finally, combining the two processes of recombination heating [Eq. (19)] and evaporative cooling [Eq. (23)], we get

$$\dot{T} = \frac{T}{3}\left(\frac{5}{3}\gamma_3\frac{N^2}{T^5} - \gamma_2 e^{-\eta}\frac{V_{ev}}{V_e}(\eta + \tilde{\kappa} - 3)\frac{N}{T}\right). \qquad (24)$$

Equations (12) and (24) form a set of coupled rate equations that describe the atom loss dynamics which we fit to our data.

C. Extension of the model to 2D evaporation

The above model was developed to explain 3D isothermal evaporation in a harmonic trap, and experiments with ^{133}Cs presented below correspond to this situation. Our model can also be extended to 2D isothermal evaporation, as realized in the ^{7}Li gas studied in Ref. [15] and presented in Fig. 1. In this setup, the atoms were trapped in a combined trap consisting of optical confinement in the radial direction and magnetic confinement in the axial direction. Evaporation was performed by lowering the laser beam power, which did not lower the axial (essentially infinite) trap depth due to the magnetic confinement. Such a scenario realizes a 2D evaporation scheme. Here, we explore the consequences of having 2D evaporation. In the experimental section, we show the validity of these results with the evolution of a unitary ^{7}Li gas.

Lower-dimensional evaporation is, in general, less efficient than its 3D counterpart. One-dimensional evaporation can be nearly totally solved analytically, and it has been an intense subject of interest in the context of evaporative cooling of magnetically trapped hydrogen atoms [23,25,26]. In contrast, analytically solving the 2D evaporation scheme is infeasible in practice. It also poses a rather difficult question considering ergodicity of motion in the trap [27]. The only practical way to treat 2D evaporation is by using Monte Carlo simulations, which were performed in Ref. [27] to describe evaporation of an atomic beam. However, as noted in Ref. [27], these simulations follow amazingly well a simple theoretical consideration, which leaves the evaporation dynamics as in 3D but introduces an "effective" η parameter to take into account its 2D character.

This consideration is as follows. In the 3D evaporation model, the cutting energy ϵ_c is introduced in the Heaviside function that is multiplied by the classical phase-space distribution of Eq. (6) [23]. For the 2D scheme, this Heaviside function is $Y(\epsilon_c - \epsilon_\perp)$, where ϵ_c is the 2D truncation energy and $\epsilon_\perp$ is the radial energy of atoms in the trap, the only direction in which atoms can escape. Now, we simply add and subtract the axial energy of atoms in the trap and introduce an effective 3D truncation energy as follows:

$$Y(\epsilon_c - \epsilon_\perp) = Y((\epsilon_c + \epsilon_z) - (\epsilon_\perp + \epsilon_z)) = Y(\epsilon_c^{eff} - \epsilon_{tot}), \qquad (25)$$

where ϵ_{tot} is the total energy of atoms in the trap and the effective truncation energy is given as $\epsilon_c^{eff} = \epsilon_c + \epsilon_z \simeq \epsilon_c + k_BT$, where we replaced ϵ_z by its mean value

$k_B T$ in a harmonic trap. The model then suggests that the evaporation dynamics follows the same functional form as the well-established 3D model, but it requires a modification of the evaporation parameter (8):

$$\eta^{\text{eff}} = \eta + 1. \quad (26)$$

Then, the experimentally provided 2D η should be compared with the theoretically found 3D η^{eff} reduced by 1 (i.e., $\eta^{\text{eff}} - 1$).

IV. DATA ANALYSIS

A. N-T dynamics and the magic η_{m}

We now perform a coupled least-squares fit of the atom number and temperature trajectories, Eqs. (12) and (24), to the data. We note that with our independent knowledge of the geometric mean of the trapping frequencies, $\bar{\omega}$, the only free fit parameters apart from initial temperature and atom number are the trap depth U and the temperature-independent loss constant λ_3. The solid lines in Fig. 1 are the fits (see Appendix D for details on the fitting) to our theory model that describe the experimental data well for a large variety of initial temperatures, atom numbers, and relative trap depth. We are able to experimentally realize the full predicted behavior of rising, falling, and constant-to-first-order temperatures.

The existence of maxima in the T-N plots indicates the existence of a "magic" relative trap depth η_{m}, where the first-order time derivative of the sample temperature vanishes.

The theoretical value of $\eta_{\text{m}}(T, N)$ is found by solving the equation $dT/dN = 0$, i.e., when $T(N)$ becomes independent on the atom number up to the first order in N. From the general structure of this equation, we see that η_{m} is solely a function of the dimensionless parameter:

$$\alpha = N \left(\frac{\hbar \bar{\omega}}{k_B T} \right)^3 (1 - e^{-4\eta_*}). \quad (27)$$

Up to a factor $(1 - e^{-4\eta_*})$, η_{m} depends only on the phase-space density $N(\hbar \bar{\omega}/k_B T)^3$ of the cloud. We plot in Fig. 2 the dependence of η_{m} vs α. Since our approach is valid only in the nondegenerate regime where the momentum distribution is a Gaussian, we restricted the plot to small (and experimentally relevant) values of α.

Using the knowledge of η_* for both ^{133}Cs and ^{7}Li, we can compare the observed values of η_{m} to the theory values of Fig. 2 (note that in the case of ^{7}Li, we plot $\eta_{\text{m}}^{\text{eff}}$, which enters into the effective 3D evaporation model). We see that for both the 3D evaporation ^{133}Cs data and 2D evaporation ^{7}Li data, the agreement between experiment and theory is remarkable.

Furthermore, in Appendix E, we show that from the three-body loss coefficients and the evaporation model, we can obtain the trap depth, which is found to be in good agreement with the value deduced from the laser power,

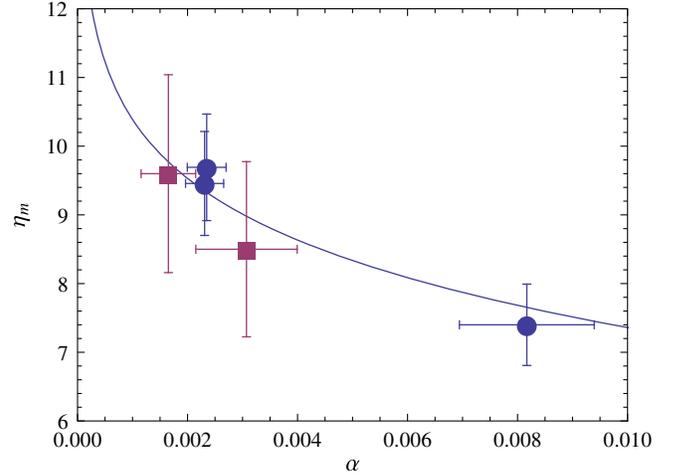

FIG. 2. "Magic" η_{m} as a function of the dimensionless parameter $\alpha = N(\hbar \bar{\omega}/k_B T)^3 (1 - e^{-4\eta_*})$ (solid line). The blue solid circles correspond to the results obtained for ^{133}Cs in Fig. 1(a) with $\eta_* = 0.098$. The red solid squares correspond to the ^{7}Li data of Fig. 1(c) with $\eta_* = 0.21$ [28]. Error bars are statistical.

beam waist, and atomic polarizability. Note that, although the theory is developed for harmonic traps, it can be applied to more complex setups (crossed dipole traps or hybrid magnetic-optical traps), where the average-energy atoms sense the harmonic part of the potential only.

We furthermore note that in an experimental situation with a finite error bar on temperature δT, and a range of atom number $\Delta N = \max N(t) - \min N(t)$, the $(dT/dN)|_{t=0} = 0$ condition can be of less practical meaning than the weaker expression $|(dT/dN)|_{\text{finite } t}| < \delta T / \Delta N$. If the atom number spread ΔN needs to be maximized at approximately constant temperature, this second condition requires a slightly higher value than η_{m} given by $(dT/dN)|_{t=0} = 0$. For instance, with $\alpha = 0.002$, $\eta_{\text{m}} = 8.2$ and $\delta T / T_{\text{in}} = 10\%$, $\eta \approx 10$ maximizes the spread in ΔN at nearly constant T.

B. Universality of the three-body loss

We now show the validity of the $L_3 \propto T^{-2}$ law for the three-body loss of unitary ^{7}Li and ^{133}Cs Bose gases. Because both species are situated at the extreme ends of the (stable) alkaline group, they have a large mass ratio of $133/7 = 19$, and the temperature range is varied over 2 orders of magnitude from $0.1\ \mu$K to $10\ \mu$K. We determine the three-body loss coefficients λ_3 from fits to decay curves such as those shown in Fig. 1. We present in Fig. 3 the results for the rate coefficient L_3, which varies over approximately 2 orders of magnitude for both species. In order to emphasize universality, the loss data are plotted as a function of $(m/m_{\text{H}})^3 T_{\text{in}}^2$, where m_{H} is the hydrogen mass. In this representation, the unitary limit for any species collapses to a single universal line [dotted line in Fig. 3, cf. Eq. (3)].

For ^{7}Li, we cover the $1-10\ \mu$K temperature range. For the temperature-independent loss coefficient, we find

FIG. 3. The magnitude of three-body loss rate at unitarity for ^{7}Li (red) and ^{133}Cs (blue), with the respective standard deviations (shaded areas). On the horizontal axis, masses are scaled to the hydrogen atom mass m_H. The dashed line represents the unitary limit [Eq. (3) with $\eta_* \to \infty$]. For comparison, we show predictions of universal theory [15] with $\eta_* = 0.21$ for ^{7}Li [28] and $\eta_* = 0.098(7)$ for ^{133}Cs as solid lines (see text). The data confirm the universality of the $L_3 \propto T^{-2}$ law.

$\lambda_3 = 3.0(3) \times 10^{-20}$ cm$^6\mu$K^{2}s^{-1}, very close to the unitary limit $\lambda_3^{max} \approx 2.7 \times 10^{-20}$ cm$^6\mu$K^{2}s^{-1}. It is also consistent with the result $\lambda_3 = 2.5(3)_{stat}(6)_{syst} \times 10^{-20}$ cm$^6\mu$K^{2}s^{-1} found in Ref. [15] with a restricted set of data, and to the prediction from Eq. (3) with $\eta_* = 0.21$ from Ref. [28] (red solid line in Fig. 3). Because the ^{7}Li data nearly coincide with the unitary limit, the value of η_* cannot be deduced from our measurements.

Furthermore, the quality of the ^{133}Cs temperature and atom number data enables us to directly measure the previously unknown η_* parameter of the 47.8-G Feshbach resonance. The standard technique for obtaining η_* is by measuring the three-body loss rate $L_3(a, T \to 0)$ as a function of scattering length in the zero-temperature limit and subsequently fitting the resulting spectrum to universal theory. However, for a given experimental magnetic field stability, this method is difficult to put into practice for narrow resonances like the 47.8-G resonance in ^{133}Cs. Instead, we use the fits to our theory model in order to obtain η_* from λ_3. We cover the $0.1-1$ μK range and find $\lambda_3 = 1.27(7) \times 10^{-24}$ cm$^6\mu$K^{2}s^{-1}. Plugging this number into Eq. (3), we deduce a value for the Efimov inelasticity parameter $\eta_* = 0.098(7)$. The corresponding curve is the blue line in Fig. 3 and is significantly below the unitary line because of the smallness of η_*. This new value is comparable to the Efimov inelasticity parameter found for other resonances in ^{133}Cs, in the range $0.06, \ldots, 0.19$ [29,30].

The plot of the full theoretical expression Eq. (2) for $L_3(m^3 T_{in}^2)$ in Fig. 3 (solid lines) requires an additional parameter describing three-body scattering around this Feshbach resonance, the so-called three-body parameter. It can be represented by the location of the first Efimov resonance position R_0 [31]. Because of the lack of

experimental knowledge for the 47.8-G resonance, we take the quasiuniversal value $R_0 = -9.73(3)r_{vdW}$, r_{vdW} being the van der Waals radius, for which theoretical explanations have been given recently [31–33]. The theory curve then displays log-periodic oscillations with a temperature period set by the Efimov state energy spacing of $\exp(2\pi/s_0) \approx 515$, where $s_0 = 1.00624$, and with a phase given by R_0. The relative peak-to-peak amplitude is 7% for ^{133}Cs with $\eta_* = 0.098$. As seen in Fig. 3, such oscillations cannot be resolved in the experimental data because of a limited signal-to-noise ratio and the limited range of temperature. Thus, the assumption of the quasiuniversal value of R_0 for the 47.8-G resonance, although strongly suggested by theory and experimental findings [30], remains to be proven. The predicted contrast of these oscillations for ^{7}Li with $\eta_* = 0.21$ is even smaller (about 6%). This is a general property of the system of three identical bosons due to the smallness of $|s_{11}|$ [15].

V. CONCLUSIONS

In this article, we have examined the coupled time dynamics of atom number and temperature of the 3D harmonically trapped unitary Bose gas in the nondegenerate regime. We have presented a set of experiments using lithium and cesium with vastly different mass and temperature ranges.

We have developed a general theoretical model for the dynamics observed, taking full account of evaporative loss and the related cooling mechanism, as well as of the universal three-body loss and heating. It is furthermore extended to the special case of 2D evaporation. We have theoretically obtained and experimentally verified the existence of a "magic" trap depth, where the time derivative of temperature vanishes both in 3D and 2D evaporation, and which only depends on phase-space density and the Efimov inelasticity parameter η_*. Our data illustrate the universal T^{-2} scaling over 2 orders of magnitude in temperature, and we obtained an experimental value of η_* for the 47.8-G resonance in ^{133}Cs. Furthermore, the theory enables an independent determination of the trap depth in the experiment. The agreement we have found here with standard methods shows that it can be used in more complex trap geometries, where the actual trap depth is often not easy to measure.

In future work, it would be very interesting to probe the discrete symmetry of the unitary Bose gas by revealing the 7% log-periodic modulation of the three-body loss coefficient expected over a factor 515 energy range.

APPENDIX A: CESIUM SETUP

Our setup is a modified version of the one presented in Ref. [34]. The ^{133}Cs atoms are trapped by means of three intersecting laser beams, and a variable magnetic-field gradient in the vertical direction (partially) compensates gravity. An intrinsic advantage of the scheme is the perfect spin polarization in the lowest hyperfine ground state $|F, m_F\rangle = |3, 3\rangle$ because the dipole trap potential is too weak to hold atoms against gravity if they are in any other ground state. As we will see, the trap frequencies stay almost constant when reducing the trap depth, making evaporation very efficient [34].

1. Trap model

The trap consists of three 1064-nm laser beams and an additional magnetic gradient field [see Fig. 4(a)]. All beams propagate in the horizontal plane. An elliptical light sheet beam [power $P_{LS} = 520$ mW, waists of $w_{LSv} = 33.0$ μm (vertical direction) and $w_{LSh} = 225$ μm (horizontal direction)] creates the vertical confinement, together with the magnetic gradient. Two round beams ($P_{R1,R2} = 1.1/1.2$ W, waist of $w_R = 300$ μm) stabilize the horizontal confinement. The light sheet center is $z_0 = 6$ μm lower than the center of the trap formed by the round beams only. The potential along the vertical axis can therefore be written as

$$V(z) = -U_{LS}e^{-[(2z^2)/(w_{LSv}^2)]} - U_R e^{-[2(z-z_0)^2/(w_R^2)]} + \gamma z,$$

(A1)

where the U_{LS} and U_R are the contributions from the light sheet and round beams, respectively. The tilt γ has a gravitational and a magnetic contribution,

$$\gamma = mg - \mu B',$$

(A2)

where m is the atomic mass, g is the gravitational acceleration, $B' = \partial_z B_z$ is the magnetic field gradient along the z axis, and $\mu = 0.75 \mu_B$ is the atom's magnetic moment in the $|3, 3\rangle$ state, with μ_B being Bohr's magnetic moment. Thus, a gradient of $B'_0 = B'(\gamma = 0) = 31.3$ G/cm is needed for magnetically levitating the cloud. An example potential shape is given in Fig. 4(b).

2. Trap frequency calibration

When we intentionally change the trap depth, we also change the trap frequencies, mostly affecting the vertical direction. The data were taken during two different measurement campaigns in 2012 and 2013. Therefore, the trap had to be recalibrated for each of these campaigns, and the data are presented in a normalized way.

We measure the oscillation frequency ω_z along the z axis as a function of the tilt [see Fig. 4(c)]. This is established by inducing sloshing oscillations to a small, weakly interacting Bose-Einstein condensate (BEC) and performing time-of-flight measurements of its position after a variable hold time.

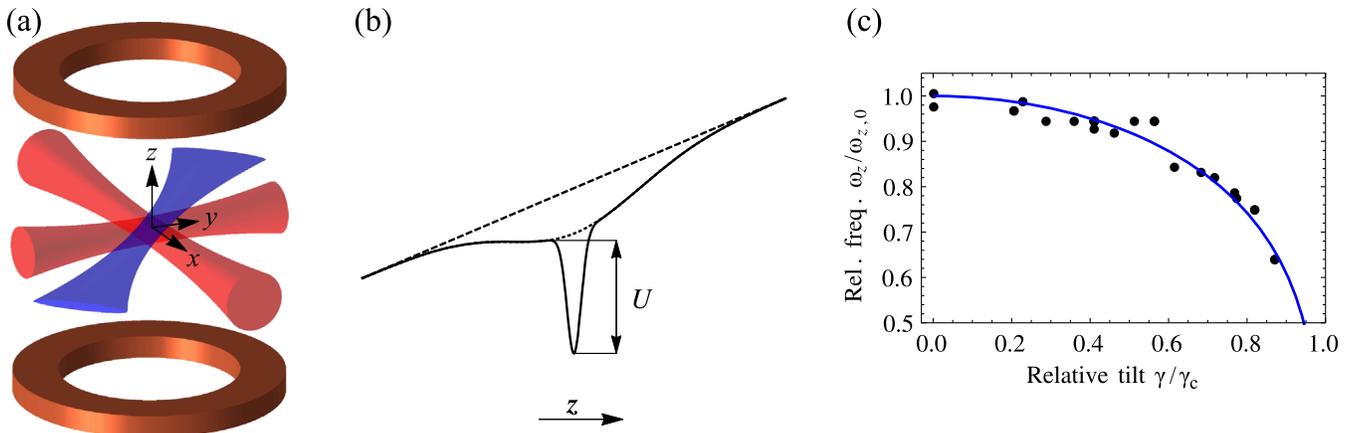

FIG. 4.   (a) Schematic drawing of the hybrid trap. It consists of three intersecting lasers, and a magnetic-field gradient in the z direction (vertical) created by a pair of coils. The light sheet beam (blue) confines dominantly along the vertical direction. The additional round beams (red) stabilize the horizontal confinement. (b) Trap shape along the vertical (z) direction. It is composed of two Gaussians and a linear contribution from the tilt [see Eq. (A1)]. Relative dimensions are to scale. Also indicated are the contributions of the tilt only (dashed line) and the round beams (dotted line). (c) Trap frequency measurements (dots) and fits (line) as a function of the tilt of the trap. The frequencies are normalized with respect to the zero-tilt frequency $\omega_{z,0} = 2\pi \times 140$ Hz. We normalize the tilt from our knowledge of the critical γ_c, where the trap opens (see text).
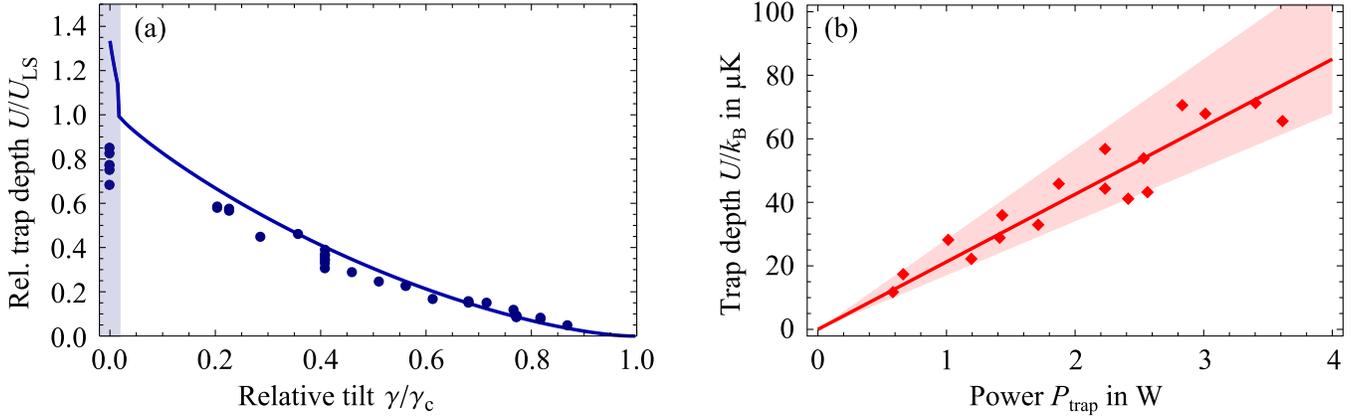

FIG. 5. (a) Relative ^{133}Cs trap-depth results from the fits to our data (dots) and theoretical model [Eqs. (A1) and (A3), line]. The trap depth is normalized with respect to the trap depth $U_{LS} \approx 11 \ \mu K$ given by the Gaussian light sheet only. The shaded area corresponds to the region where the horizontal confinement beams significantly contribute to the trap depth. (b) Absolute ^{7}Li trap-depth results from the fits to our data (dots). The solid line indicates theoretical knowledge of our trap [Eqs. (A1) and (A3), line], with $w_R = 38(1) \ \mu m$. The shaded area accounts for the combined uncertainty of w_R and P_{trap}.

We fit the measured z-axis frequencies to a numerical model of the trap potential Eq. (A1). In the model, we insert the aspect ratio of the trap depth contributions from the three beams i,

$$U_i = \frac{2}{\pi} \frac{\alpha P_i}{w_h w_v}, \tag{A3}$$

where $\alpha/k_B = 2.589 \times 10^{-12} \ \text{Kcm}^2 \, \text{mW}^{-1}$ is the atomic polarizability at 1064 nm [35], P_i is the power in beam i, and $w_{h/v}$ are the waists in the horizontal or vertical direction. We are left with two fit parameters: The frequency at zero tilt $\omega_z(\gamma = 0) = \omega_{z,0}$ and the critical tilt $\gamma_c = \gamma(B' = B'_c)$ where the trap opens [local minimum in $V(z)$ disappears] and ω_z goes to zero by construction. We find $\omega_{z,0} = 2\pi \times 139(1)$ Hz and $2\pi \times 140(1)$ Hz for 2012 and 2013, and $B'_c = -0.3(4)$ G/cm and $-4.3(7)$ G/cm for 2012 and 2013. With this calibration, we introduce the normalized tilt γ/γ_c. The values for B'_c coincide well with the gradient values observed when increasing the tilt until a small (< 5000 atoms) weakly interacting BEC drops out of the trap.

The kink in the trap depth theory curve (Fig. 5) near $\gamma/\gamma_c = 0.02$ [shaded area in Fig. 5(a)] corresponds to a situation depicted in Fig. 4(b), where the contribution of the large-waist horizontal beams on the trap depth vanishes. The blue-shaded region of the horizontal beams' contribution extends over the small region from $\gamma/\gamma_c = -0.02$ to 0.02. Therefore, small experimental uncertainties on the applied magnetic gradient, or additional trap imperfections, can explain the fact that we do not find this sudden rise in U. Other than that, we see a remarkable correspondence between theory and experiment.

We note that the data can also be well described by the analytical model of a single Gaussian potential ($U_R = 0$)

with tilt, as presented in Ref. [34]. Because of the large mismatch between w_R and w_{LS}, the presence of the round beams mainly affects the horizontal trapping. The critical gradient we find is only 2% larger than the single-Gaussian value $\sqrt{e}\gamma w_{LS}/2U_{LSv}$ [34]. Furthermore, the horizontal trapping frequencies $(\omega_x, \omega_y) \approx 2\pi \times (13, 30)$ Hz, measured with a similar method for each data set, remain constant.

3. Imaging system calibration

The high-resolution imaging system is similar to the one presented in Ref. [14]. It is well calibrated using the equation of state of a weakly interacting 2D Bose gas for the absorption-coefficient-to-atomic-density conversion (in good accordance with the method of classical 2D gas atomic shot noise [36]). The imaging magnification is obtained from performing Bragg spectroscopy on a 3D BEC, using the variable retroreflection of the 1064-nm round beams.

4. ^{133}Cs sample preparation

We prepare the ^{133}Cs samples in the trap described before. In brief, after magneto-optical trapping and degenerate Raman sideband cooling, we obtain magnetically levitated ($\gamma = 0$) samples of 10^6 ^{133}Cs atoms at 1 μK [34]. We can cool the samples further by evaporative cooling. In order to achieve this, we adjust the trap depth $U(\gamma)$ by changing the tilt γ of the potential (A1). Thus, the samples can be evaporatively cooled all the way to quantum degeneracy in ≈ 2 s [34] at 20.8 G, yielding a scattering length of 200 a_0, with a_0 being the Bohr radius [29].

We prepare our samples by stopping the evaporation at a given tilt. We then ramp the tilt adiabatically to the desired value. Finally, at a time t_0, we jump the field to the Feshbach resonance at 47.8 G [18] in typically < 1 ms and

wait for at least $2\pi/\omega_x$ in order for the samples to reach dynamical equilibrium. We are therefore able to prepare samples of variable initial parameters: Atom number N_{in}, temperature T_{in}, and relative trap depth $\eta_{\text{in}} = U(\gamma)/k_B T_{\text{in}}$, where k_B is the Boltzmann constant. After a hold time t, we take an *in situ* absorption image with a vertical imaging setup.

APPENDIX B: LITHIUM SETUP

The ^{7}Li data were taken using the apparatus described in Ref. [15]. This trap consists of a 1073-nm single-beam optical dipole trap providing adjustable radial confinement, and an additional magnetic-field curvature providing essentially infinitely deep harmonic axial confinement along the beam axis. After loading into this trap, the gas is evaporated by lowering the radial trap depth at a magnetic field of 720 G, where the two-body scattering length is 200 a_0. The evaporation in this hybrid trap is then effectively 2D. After the temperature and atom number of the gas have stabilized, the radial trap is adiabatically recompressed by about a factor of 2. Since the axial magnetic confinement is practically unchanged, this recompression causes the temperature of the gas to increase with $\omega_r^{3/2}$, while the trap depth increases as ω^2. Consequently, by varying the amount of recompression, we can vary η_{in}. After this recompression, the magnetic field is ramped to the Feshbach resonance field of 737.8 G in 100–500 ms, and $N(t)$ and $T(t)$ are measured with *in situ* resonant absorption imaging perpendicular to the long axis of the cloud. The trap shape can be described by Eq. (A1) with $U_{\text{LS}} = 0$, $w_R = 37(1)$ μm, and by replacing z by ρ, the radial coordinate. U_R is the dipole trap potential with power P_{trap}, and α is the polarizability of the ^{7}Li atoms at 1073 nm. We can neglect the tilt γ because of the small mass of ^{7}Li.

APPENDIX C: TIME SCALE ORDER

In order for the theory to be valid, we make sure the time-scale order is not violated:

$$\tau_{3B}, \tau_{\text{ev}} \gg \tau_{\text{trap}}, \tau_{2B}, \tag{C1}$$

where we have the three-body loss time constant [cf. Eq. (19)]

$$\tau_{3B}^{-1} = \frac{5}{9} \gamma_3 \frac{N^2}{T^5}, \tag{C2}$$

the evaporation time constant [cf. Eq. (24)]

$$\tau_{\text{ev}}^{-1} = \frac{1}{3} \gamma_2 \left(e^{-\eta} \frac{V_{\text{ev}}}{V_e} \right) (\eta + \tilde{\kappa} - 3) \frac{N}{T}, \tag{C3}$$

the two-body scattering time constant

$$\tau_{2B}^{-1} = n_0 \sigma_U \bar{v}, \tag{C4}$$

and the trapping time constant

$$\tau_{\text{trap}}^{-1} = \omega_{\text{slow}}, \tag{C5}$$

where ω_{slow} is the slowest trapping frequency (along z in the ^{133}Cs case).

APPENDIX D: FITS TO THE MODEL

For each data set, we have decay data for $N(t)$ and $T(t)$ from the mean values of ≈ 10 individual measurements. The error bars from Figs. 3(a)–3(c) are the 1σ standard deviations of the individual measurements. We fit both temperature and atom number individually with solutions to the coupled differential equation set of Eqs. (12) and (24). For both fits, we use a common three-body loss coefficient λ_3 and a common trap depth U. The fitting is done by minimizing the weighted sum $\alpha \chi_T + \alpha^{-1} \chi_N$ by varying both the weighing factor α and the fit parameters. The quadratic deviations are defined as $\chi_{T,N} = \Sigma \sigma_{T,N}^2$ ($\sigma_{T,N}$ being the deviations of data and the fit). This method also accounts for the different amount of relative signal-to-noise ratio of both data sets.

APPENDIX E: TRAP DEPTH

As an independent test of the theory fits, we compare the fitted trap depth U to its independently known counterpart from experimental parameters. In Fig. 5(a), we plot the ^{133}Cs results as a function of the relative trap tilt γ/γ_c. We also plot the theoretical value for $U(\gamma/\gamma_c)$ as a solid line. Except near zero tilt, we find excellent agreement of the fitted values with the values known from experimental parameters. For ^{7}Li [see Fig. 5(b)], we find excellent agreement with our theoretical knowledge of the trap depth, which is given by the dipole laser waist w_R, power P_{trap}, and the atom's polarizability. It is indicated by the shaded area in Fig. 5(b). Therefore, we can infer the dipole trap laser's waist in an independent fashion. From the fit to our measured trap depths (solid line) in Fig. 5(b), we obtain $w_R = 38(1)$ μm. This value coincides with independent measurements of w_R from fitting the trap frequencies as a function of P_{trap}. These results emphasize the validity of the theory model [Eqs. (12) and (24)].
